Abstract

Charged particle multiplicities from high multiplicity interactions of 158 GeV/nucleon Pb ions with Pb target nuclei have been measured using nuclear emulsion chambers. The characteristics of these interactions have been compared to those of central interactions of 200 GeV/nucleon proton, O, and S beams on silver or bromine targets and those from simulations using the FRITIOF 7.02 and VENUS 4.12 Monte Carlo event generators. Multiplicities of Pb+Pb interactions in the central region are significantly lower than predicted by either model. We examine the shape of the pseudorapidity distribution and its dependence on centrality in detail, because in this symmetric system the participant projectile target masses are independent of centrality,

so any dependence of the shape on centrality must therefore be a dynamical effect. VENUS, the only one of the two models which attempts to incorporate reinteraction phenomena, predicts a narrowing of the pseudorapidity distributions for the highest multiplicity events, which we do not observe. In general, FRITIOF produces better fits to the data than does VENUS.

I. INTRODUCTION

The superposition model of nucleus-nucleus (AA) interactions has been highly successful in describing the general features of particle production in high energy heavy ion systems. With the availability of beams of ^{208}Pb at the CERN SPS, superposition can now be tested over two orders of magnitude in projectile or target mass from pp to Pb+Pb, and three orders of magnitude in the number of nucleon-nucleon (NN) collisions. The Pb+Pb system provides nearly the largest reaction volume achievable, and the highest energy densities attainable until RHIC and LHC begin colliding heavy ion beams. In this paper, we report Pb+Pb results from the Krakow-Louisiana-Minnesota (KLM) emulsion chamber exposures (EMU-13) at the SPS in December 1994. Previous results from EMU-13, and a detailed description of the experiment, have been presented in refs. [1,2].

Currently, a major emphasis in this field is the search for non-superposition processes in rare events or at high energy densities. In order for a state such as a quark-gluon plasma to be produced, superposition must break down via some thermalization process, such as reinteraction. To detect and understand events in which plasma or similar collective behavior occurs, it may well be necessary to have a quantitative understanding of ‘ordinary’ superposition and reinteraction physics, especially if events exhibiting collective behavior are rare. Despite the fact that the SPS operates in an energy regime of high nuclear transparency, the Pb+Pb system is large enough that one might reasonably expect reinteraction to have

an observable effect on the distribution of produced particles in the most central events.

At the moment, we lack highly precise predictors of particle production and angular distributions in AA interactions. The simplest and historically the first such predictor is the wounded nucleon model [3], which assumes that the multiplicities n_{AA} scale with the average number of participating or ‘wounded’ nucleons W and with the average proton-proton multiplicity n_{pp} at an equivalent energy per nucleon: $n_{AA}(E) = \frac{1}{2}Wn_{pp}(E)$. This contrasts with the naive expectation that the multiplicities should scale with the number of NN interactions, which would result in multiplicities much larger than those from the wounded nucleon calculation, since a participating projectile nucleon typically interacts with several target nucleons (~ 5 in central Pb+Pb interactions). At SPS energies, the wounded nucleon model predicts multiplicities which are systematically lower than those observed [4-6], but only by $\sim 15\%$ for all measured systems from pp to Pb+Pb. In fact, the current generation of Monte Carlo codes are no better at predicting multiplicities in ultra-heavy systems than the wounded nucleon model, although they do of course provide much more comprehensive predictions of angular distributions, transverse momenta, secondary particle species, etc.

At high energy, individual projectile nucleons should typically interact with several target nucleons before re-hadronizing outside the target nucleus. Thus, the physical implication of the relative success of the wounded nucleon model is that interactions of hadronic excitations (‘reinteractions’ of the collision products emerging from the initial NN interactions) appear to contribute little to the final-state multiplicity. To look for dynamical effects besides this interesting but well-known ‘wounded nucleon effect’, and to study reinteraction effects in detail, one needs to characterize the multiplicities of AA systems carefully. This paper characterizes the measured Pb+Pb multiplicities and angular distributions and compares them to lighter systems and to predictions from FRITIOF 7.02 [7] and VENUS 4.12 [8]. Other experiments, both electronic [9-13] and emulsion [14-16], have reported measurements of high energy Pb+Pb interactions, including results on multiplicities, strangeness and J/ψ production, flow, intermittencies, etc. Measurements made with nuclear emulsions have

the unique advantage that their excellent position resolution makes it possible to study the extreme forward direction where the projectile spectators appear [1]. In this study we separate the central region, where effects unique to AA interactions are thought to occur, from the spectator region. Both regions are examined for predicted signs of reinteraction.

In Sec. II we calculate the number of wounded nucleons W . Then in Sec. III we describe the experiment and analysis procedure, and use the measurement of forward charge to demonstrate the validity of the calculation of W . At the same time, we derive a value for the charged particle multiplicity n_0 in the absence of spectators, a value which appears to be lower than expected from the simulations. In the framework of the wounded nucleon model, n_0 is proportional to W . The multiplicity per wounded nucleon m is therefore independent of W and as a result also independent of impact parameter, so that m is an appropriate quantity to test for effects unique to AA collisions. In Sec. IV, we compare the measured value of m for central Pb+Pb collisions to the FRITIOF and VENUS simulation results, to the results of pN interactions at similar energies, and to the results for other AA systems. In Sec. V we look at the detailed shapes of the pseudorapidity distributions and find a distribution which is broader than predicted by VENUS (either with or without reinteraction) but similar to that predicted by FRITIOF without reinteraction. We then look in the forward region and use the measured shape of the produced particle distribution to separate out the spectators and derive an average transverse momentum for the spectator protons.

II. CALCULATION OF THE NUMBER OF PARTICIPANT NUCLEONS

In comparing multiplicities in systems of different sizes, a convenient quantity is the multiplicity per participating nucleon $m = n/W$. In the context of the superposition model, this expression factorizes the observed multiplicity n into two quantities W and m . W , the number of wounded nucleons, contains all the geometrical effects, i.e., the effects of nuclear radii, density, and impact parameter. The other factor, m , depends only on interaction

dynamics. The calculation of W from the experimental data is described here.

For inclusive datasets, the number of participants, or wounded nucleons, is given in terms of interaction cross sections σ by [3]

$$W = A_T \frac{\sigma_{NP}}{\sigma_{PT}} + A_P \frac{\sigma_{NT}}{\sigma_{PT}} \quad (1)$$

Here the subscript P means projectile, T means target, and N denotes an individual nucleon, so that σ_{PT} is the total inelastic hadronic cross section for the projectile nucleus interacting with the target [17 - 19], and σ_{NP} and σ_{NT} are the corresponding nucleon-nucleus cross sections. The first term in (1) is the number of wounded target nucleons W_T and the second the number of wounded projectile nucleons W_P . To compute W for central data samples, one uses cross sections which are functions of the maximum impact parameter b_{max} of the sample. The cross sections are computed with a Glauber calculation [20], using the inelastic hadronic cross sections and the nuclear density functions of the target and projectile. The maximum impact parameter of the data sample is derived from the partial cross section for producing events in the sample,

$$\sigma_{part} = \pi b_{max}^2 = \sigma_{PT} \frac{N_{cent}}{N_{tot}} \quad (2)$$

where N_{cent} is the number of central events in the data sample and N_{tot} is the total number of hadronic AA interactions. N_{tot} is derived either from a minimum bias scan of the emulsions or is calculated from the beam count and the total AA cross section. The Glauber calculation gives the number of participant or ‘wounded’ projectile and target nucleons W_P and W_T . One can also calculate the number of target and projectile interactions ν_T and ν_P with the same formalism by assuming that the cross section for nucleons which have been excited by a previous interaction is the same as for unexcited nucleons, σ_{NN} . This assumption is not necessary in the calculation of the number of participants $W = W_T + W_P$, which depends (through σ_{NP} , σ_{NT} , and σ_{PT}) only on σ_{NN} and the nuclear density functions. In this analysis we use numbers of participants and numbers of collisions derived from the FRITIOF simulations [7] of the nuclear collision geometry for the specified maximum impact

parameters (Eq.2). The sample of central events discussed here corresponds to impact parameters less than 5 fm, compared to a maximum of $2.4(208)^{1/3} \sim 14$ fm for Pb+Pb. At $b = 5$ fm, the values of W derived from different density functions differ by $\sim 3\%$ or less [21]. The deviation increases for larger impact parameters.

III. EXPERIMENTAL AND ANALYSIS PROCEDURE

The data chosen for this analysis consist of central interactions on targets at least as heavy as the projectile. In these systems, the multiply charged spectator fragments that remain after the interaction provide an indication of the centrality of the collision. The measurements are taken from two different kinds of emulsion experiments. Data from 200 GeV p+Ag/Br [22], O+Ag/Br [23], and S+Ag/Br [23,24] collisions were measured in emulsion stacks, in which the detector was the target, and which consequently had 4π angular acceptance. A sample of 170 events from 158 GeV/nucleon Pb+Pb collisions obtained in CERN experiment EMU-13 was measured in chambers with Pb targets and thin emulsion plates exposed perpendicular to the beam[1]. The Pb chambers were designed specifically so that charge could be measured in a small inclined stack at the downstream end of the chambers [1,2]. In the chambers we measure only the particles in the forward cone, $\theta \leq 0.11$ radian, corresponding to a pseudorapidity $\eta \geq 2.9$. This cone includes the peak of the pseudorapidity distribution. Chambers allow the use of targets other than emulsion, and also present less material to induce secondary interactions. In both emulsion chambers and stacks, individual particles can be measured even in the extreme forward region, and the sub-micron resolution makes it possible to identify the individual tracks of these particles and to measure their individual charges.

In the stacks, heavily ionizing particles (those with ionization greater than 1.4 times minimum) are distinguished from relativistic shower particles, and the numbers of each, N_h and n_s , are recorded. Two selections on the minimum bias sets are made to select central events on heavy targets [5,24]: interactions on the Ag or Br nuclei in emulsion are selected

by choosing those events with $N_h > 15$ heavy tracks produced by slow particles from the target, and central events are chosen by selecting those events with no multiply charged beam fragments ($n_{fr} = 0$).

In the analysis of the Pb chambers, no minimum bias scan was performed. Instead, a sample of high multiplicity events was selected by visually scanning for large events. This scan efficiently detected events with observed charged multiplicities > 600 (corresponding to total charged multiplicities larger than about 1000) together with an incomplete sample of events with smaller multiplicities [1]. From the measured number of incident primaries and the assumed total hadronic Pb+Pb cross section, $\sigma_{Pb+Pb} = 6.9 \pm 0.5$ barns, we estimate that we have measured $(23 \pm 4)\%$ of the hadronic interactions. In 170 events we have fully measured all the particles in the pseudorapidity cone $\eta \geq 2.9$ using an automated measurement system developed at LSU [25,26]. The measurements of the multiplicities of these events have a systematic uncertainty of 3%.

The charge modules included in the EMU-13 chambers enabled us to make a measurement of the individual charges of the forward emitted projectile fragments [2]. These measurements were made in the most downstream module of the chamber by counting δ -rays along the particle tracks. The δ -ray counts were taken on a track length of about 3 mm, giving a charge uncertainty of the order of 1-2 charge units for fragments with charge $Z < 30$. These charge measurements were completed for 152 of the central Pb+Pb collisions. In the remaining 18 events, the produced fragments missed the charge section of the chamber, making individual δ -ray counts impossible. For these events we assigned charges to multiply charged fragments by using the darkness measurements which were made for the all recorded particles downstream from the interaction vertex. These darkness measurements were used in our preliminary analysis of central Pb+Pb collisions [1] to separate singly charged particles from the multiply charged projectile fragments, and correlate nicely with the charge estimates obtained from the δ -ray counts, as is shown in Fig. 1. Therefore we used the parameterization of the track darkness vs. charge shown in Fig. 1 to assign charges to fragments produced in the 18 events which did not reach the charge section of the cham-

ber. This parameterization was also used to estimate charges for 7 fragments recorded in our sample of 170 events, which underwent a secondary interaction in the upstream elements of the chamber. Over all the analyzed events, we observed 540 helium fragments ($Z=2$) and 175 heavier fragments. The average charge of those fragments with $Z > 2$ is small, 5.3 ± 0.3 , as compared to 16.1 ± 0.6 measured in inclusive Pb+Pb interactions [2]. The frequency of projectile fragments with $Z > 2$ is also lower in the selected central collisions, about 1 fragment per event, while in inclusive interactions we observe on average twice as many such fragments per collision. The measurements of the individual charges of the projectile fragments allow us to define for each analyzed event the quantity $Z_b = \sum_{i=1}^{n_{fr}} Z_i$, the total charge bound in multiply charged fragments. This quantity is proportional to the size of the projectile spectator remnant, and therefore is a good measure of the impact parameter of the collision. Details of the chamber measurements and the automatic measurement system are presented elsewhere [1,2,22-26].

The measured multiplicities of the Pb+Pb events must be scaled by an angular acceptance factor to calculate the total produced multiplicities n_{prod} . To determine the acceptance factor, pseudorapidity space is divided into three intervals: $\eta < 2.9$, in which multiplicities are not measured and must be estimated; $2.9 \leq \eta < 6$, in which all events are completely measured, and which is virtually spectator-free; and $\eta \geq 6$, which is also measured but which contains spectators as well as produced particles. In the interval $2.9 \leq \eta < 6$, the shapes of the pseudorapidity distributions are independent of the events' overall multiplicity and are reproduced quantitatively by FRITIOF. (See ref. [1] and Section 4.) We therefore use a single acceptance multiplier derived from FRITIOF for events of all multiplicities: $n_{prod}/n_{2.9-6} = 1.80$. We note that we obtain the same multiplier if we use VENUS instead of FRITIOF, even though VENUS produces narrower distributions. This is a consequence of the symmetry of the rapidity distribution for the Pb+Pb system. Because we measure pseudorapidity η rather than rapidity y , there is an uncertainty in the position of the pseudorapidity peak, due to the non-zero mass and transverse momentum of the produced particles. This shift $\eta_{peak} - y_{peak}$ is observed to be 0.3 ± 0.1 units of pseudorapidity. The 0.1 uncer-

tainty in the pseudorapidity corresponds to an uncertainty in the multiplier of 2.5%. The overall uncertainty in the Pb+Pb estimates of multiplicity, including the 3% measurement uncertainty, is 4%.

The Pb+Pb data samples used in the analysis are shown in Table I. We tabulate the mean bound charge $\langle Z_b \rangle$, the mean singly charged and fragment multiplicities $\langle n_{prod} \rangle$ and $\langle n_{frag} \rangle$, and the forward ($\eta \geq 6$) charge $\langle Q_{\eta \geq 6} \rangle$ for a set of samples selected by different values of Z_b . Note that these event samples are independent. The sample of events with $n_{prod} \geq 1000$ (corresponding to 9.7% of the total interactions) is compared to data from interactions of lighter 200 GeV/nucleon projectiles on silver or bromine (Ag/Br), summarized in Table II, where the average number of intranuclear interactions in the events covers the range from 4.2 for p+AgBr to 767 for Pb+Pb.

In the samples of central and semi-central events in Table I, there are only small numbers of spectator protons in the projectile region [1]. Almost all the shower particles in this region are ‘produced’ in the sense that they are either created or are participant protons, which may originate from either incident protons or neutrons. In the stack data sets, heavily ionizing particles are found in the large-angle target region and are excluded from the analysis in order to remove fragments and spectator protons coming from the target spectator. This cut also removes a few produced particles, estimated from VENUS and FRITIOF to be of the order of 2 – 3% of the charged particle multiplicity. Since the Pb+Pb analysis is restricted to the region $\eta \geq 2.9$, heavy target fragments are almost completely excluded from these Pb+Pb data.

In both the stacks and the chambers, the centrality selection is made by cutting on the number and charge of beam fragments, which determine Z_b . In the case of the Pb + Pb chamber measurements, however, because the beam and target are of equal size, Z_b is a variable centrality selection which is more sensitive to the centrality than in the other, asymmetric, systems. Fig. 2 shows the multiplicities and the dispersions of the multiplicity distributions as a function of Z_b . In the simulations, the Z_b selection is modeled by choosing a range of impact parameters corresponding to the number of events in the sample (Eq. 2).

The FRITIOF and VENUS points are therefore plotted for fixed values of impact parameter b . The data points are plotted for the corresponding values of Z_b . For both the data and the simulations, the event multiplicities decrease with increasing Z_b , demonstrating that events with smaller charge bound in the projectile fragments do indeed have a larger number of participants, and on average are more central. The FRITIOF and VENUS events follow the same trend as the measured events, but with higher multiplicities overall.

The difference in multiplicity in Fig. 2(a) between the measurements and the simulations is at least partly due to the different selection criteria applied to the two data sets. Fig. 2(b) shows the standard deviations σ of the multiplicity distributions in each data sample. The measured distributions are broader than those predicted by the simulations, at least partly due to our modeling assumption that samples with a particular charge bound in projectile fragments correspond to a well-defined range of impact parameters. This assumption is to some degree physically unrealistic. Instead, we expect there to be some overlap in impact parameters between samples of different Z_b , and consequently the measured data points correspond to broader impact parameter ranges than do the corresponding simulated events. This deviation from the ideal selection assumed for modeling purposes has an impact on the results in Fig. 2. Nevertheless, Fig. 2 clearly shows that Z_b correlates reasonably well with impact parameter.

The symmetry of the Pb+Pb system, combined with the high multiplicities of these events, allows us to test our Glauber calculations and at the same time look in some more detail at the comparison of measured and calculated multiplicities. In Fig. 3, we plot the total charge contained in the cone $\eta \geq 6$, which includes essentially all of the spectators, against the multiplicity $n_{prod} = 1.80n_{2.9-6}$ for all the analyzed events. Superimposed on the data above $n_{prod} \geq 1000$ (where the selection is close to 100% efficient) are the averages for samples with different values of Z_b (solid circles), i.e., centrality. The charge intercept of a fit to the Z_b points (upper line) is 79 ± 3 , consistent with the charge of the Pb beam, demonstrating that indeed all the spectator charge is contained in the $\eta \geq 6$ cone, as asserted above. For each sample, the calculated spectator charge $82(A - W_P)/A$ (where $A = 208$

is the projectile atomic number) has been subtracted from the measured total charge to obtain the average produced multiplicities in the $\eta \geq 6$ cone (large triangles). This charge grows with the multiplicity in a manner consistent with direct proportionality (cf. Section 4). This scaling is observed in the Pb+Pb system at lower, spectator-free pseudorapidities than in the p, O, and S+AgBr systems, and is another consequence of the Pb+Pb system's symmetry. This simply means that the shape of this system's pseudorapidity distributions are independent of multiplicity (and centrality). The forward charge data are consistent with the assumption that this behavior also holds in the spectator region. It also suggests that event multiplicity is directly proportional to the number of participants, as expected.

The intersection of the two fitted lines at $n_{prod} = 1584 \pm 60$ determines the multiplicity¹ of events with no spectator protons n_0 . This value agrees with the value determined directly from the $n_{prod} \geq 1000$ sample, $2A/W \langle n_{prod} \rangle = 1545 \pm 53$. Thus, the forward charge measurements, the produced particle measurements, and the calculated number of participants together form a tightly consistent picture. If our calculations of the numbers of participants are systematically wrong by as little as $\sim 4\%$, our two methods of determining n_0 will no longer agree. Fig. 3 therefore indicates that our participant calculations are correct within the stated errors.²

¹Head-on Pb+Pb events have on average about 9 spectator protons, and therefore have slightly lower multiplicities than zero-spectator events.

²This conclusion depends on the assumption that produced multiplicity can really be plotted as a straight line through the origin as in Fig. 3. Although plausible, this assumption should be tested by extending the data points in Fig. 3 to the left (i.e., to more peripheral events). Our scanning procedure, which was not fully efficient for detecting events with multiplicities smaller than 1000, makes this test impossible. Nevertheless, the good fit of the triangles in Fig. 3 with a straight line through the origin strongly suggests that this assumption is reasonable. The linearity assumption (as suggested by the wounded nucleon model) is discussed and justified further in sec. V.

The spectator-free multiplicity measured here (1584 ± 60) agrees well with the value of 1550 ± 120 determined from the preliminary analysis in [1], and is lower than the value of 1850 expected from the Monte Carlo simulations. We note that results reported by Stenlund et al. [14] have also suggested a lower central Pb-Pb multiplicity than expected. We have repeated our analysis by fitting to points chosen on the basis of the number of alphas rather than Z_b , the number of shower particles n_s , and with different radial density distributions, and obtain essentially identical results in all cases. The conclusions that the analysis is self-consistent and that the spectator-free multiplicity is lower than expected appear to be robust and independent of the detailed analysis.

The advantages of emulsion chambers over stacks are that they allow us to choose our target and minimize secondary interactions. The main shortcomings of chambers, namely their limited angular acceptance and the relative difficulty of performing minimum bias scans, turn out to be only minor disadvantages for the study of central events because of the symmetry of the Pb+Pb system and the good statistics in individual events. Symmetric projectile-target systems, such as the Pb+Pb system, are unique in providing a high quality, variable centrality criterion.

IV. MULTIPLICITIES PER PARTICIPANT

In order to compare the multiplicities measured with different beam-target combinations, we can use the calculated number of participants to determine the multiplicity per participant for each of our four beam-target systems. Table III shows the average shower particle multiplicities per participant $m_s = n_s/W$ for the four central data sets of Table II. The first three systems are at 200 GeV/nucleon, and the Pb+Pb is at 158 GeV/nucleon. In the framework of the wounded nucleon model, the average number of produced particles per participant $m_{prod} = n_{prod}/W$ is independent of impact parameter. To obtain the quantity n_{prod} , the measured quantity n_s is corrected by subtracting the number of spectator protons and adding the number of produced slow ($\beta < 0.7$) particles. The average number of

projectile spectator protons n_{spect} is estimated from the Glauber calculations. The average number of heavily ionizing slow produced particles is estimated from FRITIOF or VENUS.

Since the FRITIOF and VENUS predictions for the number of slow particles are different, we obtain two values for m_{prod} : one corrected with FRITIOF and one corrected with VENUS. These are listed as $m_{prod}(Data)$ in Table III together with the two model predictions labeled $m_{prod}(Simulations)$. The two models give similar results for the heavy ion beams, but due to reinteraction, VENUS predicts a substantially larger multiplicity per participant for the proton beam than does FRITIOF. Both model predictions slightly overestimate the respective measured multiplicities of the O+Ag/Br and S+Ag/Br, and predict significantly too many charged particles in Pb+Pb events. FRITIOF's over-prediction of multiplicities in the Pb+Pb system is also discussed in Ref. [1]. However, we note that in the case of Pb + Ag/Br [27], where the target is significantly lighter than the projectile, the total measured multiplicities of high multiplicity events are consistent with the predictions.

Table III also shows the charged multiplicities per participant $m_{pn} = n_{pn}^{\pm}/2$ for pn interactions at similar energies [28,29]. We compare to pn data rather than pp data since the pn system is more similar to the AA data in isospin content and charge fraction, both of which affect the NN multiplicities at the 10% level. FRITIOF and VENUS both produce almost equal numbers of protons and neutrons, which is not the case for pp or nn interactions, but is true of pn interactions. In agreement with other studies, we find that the data are systematically higher than predicted [5,6]. Table III appears to indicate that the Pb+Pb value is significantly closer to the wounded nucleon model prediction than are those for the other systems. However, we note that the Pb+Pb system has a significantly different isospin mixture (i.e., a larger neutron excess) than the other systems, which may somewhat reduce its charged multiplicity relative to the other more proton-rich systems. Nevertheless, m_{Pb+Pb} is lower than predicted by both Monte Carlos, and by empirical extrapolations from lighter systems [4,30].

Fig. 4 displays the shower multiplicity densities as a function of pseudorapidity. For each system, the densities have been normalized by the calculated number of wounded nucleons

for the data sample. The same normalizations are used for the data and the models. The error bars include uncertainties due to finite counting statistics and uncertainties in the systems' b_{max} (which propagates into the uncertainty in W), added in quadrature. The most obvious conclusion from this figure is that the Pb+Pb system has a significantly lower measured peak density than predicted by either model. Qualitatively, this appears consistent with the trend from lighter to heavier systems. The models slightly underestimate the p+Ag/Br central region, overestimate the O+Ag/Br and S+Ag/Br peaks, and significantly overestimate Pb+Pb. FRITIOF provides the better fit in every case.

We have examined the effects of reinteraction predicted by VENUS with separate runs in which reinteraction has been turned off, without adjusting any other parameters in the model. These runs are represented in Fig. 4 by the dotted lines. As expected, reinteraction improves the p+Ag/Br fit in the target region [31]. However, turning reinteraction off does not improve the fit to the AA data at midrapidities. This result is discussed in more detail in the next section.

The hypothesis of limiting fragmentation [32,33] states that in hadronic interactions, the density in the target region is asymptotically independent of beam energy and projectile species. When the projectile region is measured in the target rest frame, it is shifted by a kinematically determined amount y_{beam} , but the projectile region densities are otherwise predicted to be independent of energy and target species. This approximate invariance has been observed in pp , $\bar{p}p$, pA , and π -emulsion interactions [34-37]. The natural combination of this hypothesis with the principle of incoherent superposition in AA collisions would state that the target region scales with the number of wounded target nucleons W_T and the projectile region scales with the number of wounded projectile nucleons W_P [38]. This expectation is tested in Fig. 5, which shows the shower densities per wounded target nucleon in Fig. 5(a) and the densities per wounded projectile nucleon in Fig. 5(b). Proton-hydrogen data from the NA22 bubble chamber experiment [39] are shown for comparison to the emulsion data. Fig. 5 demonstrates that wounded nucleon scaling is quite a good approximation only for AA systems. There appear to be some deviations from this scaling for pp and pA collisions,

but these differences must be interpreted cautiously. First, energy degradation of the projectile passing through the target is significantly different for pp , pA , and AA interactions. In addition, there are different spectator contributions. The bubble chamber acceptance corrections are highest in the projectile region, and the acceptances for slow particles in the target region differ between the two techniques. The p+Ag/Br data are lower than the O, S, and Pb data in the projectile fragmentation region, but the excesses in the AA systems are consistent with the calculated number of spectator protons in these systems. There are no projectile spectators in p+Ag/Br interactions. The difference between the p+Ag/Br data and the AA systems in the target regions appears to be real, and may be due to reinteraction. Nevertheless, over a range of nearly two orders of magnitude in W and $dn/d\eta$, the variation in $\frac{1}{W}dn/d\eta$ is only ~ 0.3 . The pseudorapidity densities are parameterized quite well with just W_T and W_P . Dynamical effects apparently have only a minor effect on the angular distributions in AA systems in this energy range.

In conclusion, multiplicities in the Pb+Pb system are lower than predicted either by FRITIOF or VENUS, although FRITIOF does significantly better than VENUS. The discrepancy is primarily in the central region. The distributions in the spectator regions appear to be reasonably well understood as the result of fragmentation of W_P or W_T wounded nucleons. We observe no other dynamical effects in the spectator regions except in the p+Ag/Br system, where we may be observing the effects of reinteraction in the target region.

V. SHAPES OF PB+PB PSEUDORAPIDITY DISTRIBUTIONS

In the Pb+Pb system, the shapes of the shower pseudorapidity density distributions are independent of multiplicity over most of the observed region of pseudorapidity space. This behavior is illustrated in Fig. 6 using the full Pb+Pb data set. The forward region ($\eta \geq 6$) is the sole exception to this rule due to the presence of spectator protons, especially in the more peripheral (lower multiplicity) events. Fig. 7 shows the total charge enclosed in the $\eta \geq 7$ and $\eta \geq 8$ cones. (The $\eta \geq 6$ cone is shown in Fig. 3.) The relationship between enclosed charge

and multiplicity is consistent with linearity in all three cones. Thus, the data in the forward region are consistent with a linear two-component model, in which the produced multiplicity is directly proportional to multiplicity, just as in Fig. 6, while the spectator contribution decreases linearly with multiplicity from the most peripheral events to the most central ones. These linearities are predicted by FRITIOF, and are a consequence of superposition in symmetric systems. They hold as long as second-order effects, i.e., reinteraction, are unimportant.

VENUS models particle reinteraction, providing an expectation for the influence of reinteraction on the pseudorapidity distributions. Fig. 8 relates the peak pseudorapidity density $(dn_s/d\eta)_{peak}$ of the Pb+Pb events to their total produced multiplicity n_{prod} . The straight line shows a linear fit to the data: The data are consistent with direct proportionality between $(dn_s/d\eta)_{peak}$ and n_{prod} . The VENUS simulated events, superimposed on the data in Fig. 8(a), deviate from linearity and differ significantly in shape from the data at high multiplicity. This deviation can also be seen in Fig. 4, where VENUS predicts a narrower and taller distribution for central events than is observed. In Fig. 8(b), the data points are suppressed for clarity, but the same straight line fit as in Fig. 8(a) is compared to VENUS with reinteraction turned off, but otherwise run with the same parameters. VENUS is more consistent with the data when reinteraction is turned off, although at high multiplicities VENUS still predicts too high a central peak. For the case of central Pb+Ag/Br collisions as well, a wider distribution than expected from VENUS was observed [27,40]. The best fit to the shape of the distribution is shown in Fig. 8(c), where the FRITIOF predictions are shown to be completely consistent with the linear fit to the data.

The data are therefore consistent with two conclusions: (1) the shape of the produced particle multiplicity in the spectator region is independent of multiplicity, as it is from $\eta = 2.9$ to $\eta = 6$, and (2) the shape of the spectator proton distribution is independent of multiplicity. If these conclusions are correct, then we can statistically separate the produced and spectator distributions. Let us define $f_{prod}(\eta)$ and $f_{spect}(\eta)$ to be the normalized produced particle and spectator proton distributions, respectively. We normalize $f_{prod}(\eta)$ to integrate to one in the

interval 2.9-5.5, a region which excludes essentially all spectators, and normalize $f_{spect}(\eta)$ such that it integrates to one over $\eta \geq 6$. Then the average pseudorapidity distribution $\rho_{samp}(\eta)$ of a sample of events is

$$\rho_{samp}(\eta) = a_{samp}f_{prod}(\eta) + b_{samp}f_{spect}(\eta), \quad (3)$$

where b_{samp} is the number of spectator protons per event in the sample, and a_{samp} is related to the produced multiplicity through the fraction of particles produced in the interval $\eta = 2.9 - 5.5$: i.e., $a_{samp} \sim 0.52n_{prod}$. If we measure the distributions of a central and a semi-central sample, $\rho_{cent}(\eta)$ and $\rho_{semi}(\eta)$, we can infer the shapes of the produced and spectator proton distributions. For example,

$$f_{spect}(\eta) = \frac{a_{semi}\rho_{cent}(\eta) - a_{cent}\rho_{semi}(\eta)}{a_{semi}b_{cent} - a_{cent}b_{semi}} \quad (4)$$

Note that only a_{semi} and a_{cent} affect the shape of the resulting distribution; the numbers of spectators in the two samples b_{semi} and b_{cent} enter only into its normalization.

Our central sample for this analysis is the $Z_b \leq 4$ sample. The semi-central sample consists of those events with $Z_b > 4$. The a coefficients are simply the areas under the samples' measured distribution between $\eta = 2.9$ and $\eta = 5.5$. The b coefficients are evaluated using Fig. 3, which relates the mean multiplicity of each sample to its mean spectator charge Q_{spect} in the $\eta \geq 6$ cone. Subtracting the bound charge Z_b gives us an estimate of the number of spectator protons in each sample, which is the same as b_{samp} .

Fig. 9(a) shows the resulting spectator distribution $f_{spect}(\eta)$. Fig. 9(b) shows the same distribution as a function of θ rather than η . The θ distribution can be fitted to a gaussian with a half-width of 1.82 ± 0.39 mrad ($\chi^2 = 0.6$), as shown in Fig. 9(b). For spectators having the same longitudinal momentum as the beam, this width corresponds to an r.m.s. transverse momentum of (290 ± 60) MeV/c.³ This is significantly larger than would be expected from an isotropic evaporation model (140 MeV/c). We can also fit the observed

³Presumably, the longitudinal momentum (p_l) distribution is at least as broad as the p_t distri-

distribution to a sum of a Gaussian with a width of 140 MeV/c plus a second Gaussian peaked at $\theta \sim 3$ mrad, corresponding to $p_t \sim 470$ MeV/c. In either case, there is evidence for a wider distribution than expected. Thus, the spectator distribution suggests that there is a rescattered component. This scattered component, however, is small: the contribution of a second Gaussian to the total is no more than $\sim 20\%$ of the total.

The derived spectator distribution is consistent with our other results. The distribution has a small tail extending beyond $\eta = 6$ ($\theta \sim 5$ mrad), indicating that the spectator charge residing outside the $\eta \geq 6$ cone is very small, in agreement with the charge intercept in Fig. 3. The derived produced particle distribution has almost the same shape as that of the central sample, but has a slightly smaller tail, as expected (Fig. 10). We note that the spectator correction improves the agreement between the Pb+Pb and the p+Ag/Br projectile regions in Fig. 5.

In summary, the data are consistent with the shape of $dn_{prod}/d\eta$ being independent of multiplicity over the entire range of pseudorapidity. This independence is directly observed in the central region, where there is no spectator contribution. This result is unexpected in light of the VENUS simulations, and appears to indicate that reinteraction has little influence on the produced particle distribution. On the other hand, the typical p_t values derived for spectator protons are between typical Fermi momenta (~ 100 MeV/c) and proton scattering p_t values (~ 450 MeV/c), suggesting that reinteraction plays a role in scattering or heating the residual spectators.

bution (in the beam rest frame). In this case, the lab-frame p_t distribution will be quite broad, having a significant tail below 100 GeV/c. Thus, our assumption that the spectator protons are a mono-energetic beam is not entirely realistic. This may cause us to overestimate the r.m.s. transverse momentum. In this case, the observed effect is due to a decreased longitudinal momentum of the spectators.

VI. DISCUSSION AND CONCLUSIONS

Among high energy heavy ion systems studied to date, the 158 GeV/nucleon Pb+Pb system is unique in its combination of symmetry with large multiplicities, and consequently high track statistics in individual events. We have exploited both of these properties in studying centrality criteria, forward multiplicities, and shape-multiplicity dependence. Because of the symmetry of the Pb+Pb system, any shape changes in the pseudorapidity distributions must be due to reinteraction or the onset of non-superposition effects, rather than changes in collision geometry. However, we find no evidence for shape changes. Our analyses by no means rule out the occurrence of reinteraction, but taken together, they place stringent limits on rescattering effects in the Pb+Pb system as they might appear in multiplicity or pseudorapidity density measurements. Our study of forward multiplicities of individual events gives us confidence in our participant estimates, and also allows us to plausibly extract information on the transverse momenta of spectator protons. These features of the dataset are summarized in Fig. 3, which brings together the relationships between the multiplicities of central events, forward charge, number of participants, and beam charge.

Perhaps the most interesting finding presented here is the independence of the pseudorapidity shape and the centrality of the collision. This apparently implies that at SPS energies, particle production in the center of mass is not significantly more isotropic in central events than it is in peripheral ones, even in ultra-heavy systems. This contrasts with the results from the AGS at 14.6 GeV/nucleon, where pseudorapidity densities from heavy ion interactions become roughly isotropic at the highest multiplicities [41]. Near 200 GeV/nucleon, this anisotropy holds not only in the central region but also in the spectator regions, where we observe scaling with the number of participating projectile or target nucleons: the initial geometry of the system is reflected in the final state.

The fact that rescattering-induced narrowing is predicted to occur but is not observed is puzzling in light of evidence for rescattering from other experiments [42-44]. In VENUS, the narrowing of the distribution with reinteraction occurs because of a combination of greater

proton stopping power, slower pions, and enhanced heavy particle production ($\bar{p}p$ pairs and kaons) in the central region. Fig. 11 shows the interplay of these effects. Note that the energy for additional heavy particle production comes in part from increased nucleon slowing, and also a slight reduction in pion production. The absence of narrowing in central events may indicate that the degree of slowing of protons and pions in Pb+Pb events is less than the model predicts. Without the additional energy available for particle production which comes from increased nucleon stopping power, increased heavy particle production would come at the expense of smaller pion yields. Thus, reinteraction-induced heavy particle production accompanied by a more modest increase in stopping power could explain both the observed shape independence and the low multiplicities.

In conclusion, it seems clear that in general FRITIOF provides a better simulation of the data than does VENUS. This is particularly noticeable for these very massive Pb+Pb interactions, and becomes less noticeable for the lighter nuclei. The average multiplicities and pseudorapidity distributions in central AA interactions on heavy targets at SPS energies are mainly determined by the number of participating nucleons. Multiplicities in these collisions are nonetheless higher than would be expected by simply scaling NN multiplicities at the same energy, indicating a dynamical effect at work in addition to the wounded nucleon effect. The dependence of this excess on system mass is not well-predicted by the Monte Carlo event generators. The Pb+Pb pseudorapidity distributions appear to have a shape which is independent of multiplicity, placing an important constraint on models of reinteraction in the central region. Indeed, no direct evidence for reinteraction is observed in the central region. However, we do find evidence for reinteraction of produced particles or excited matter on the spectators.

FIGURES

FIG. 1. Correlation between the darkness measurements on the Pb projectile fragments and their charges estimated from the number of δ -rays counted along the fragment tracks in the charge section of the EMU-13 chambers.

FIG. 2. a) Measured mean multiplicity and b) standard deviation of Pb+Pb events selected by the charge Z_b bound in the multiply charged projectile fragments (solid circles). Simulated events are selected by impact parameter (open symbols).

FIG. 3. Forward charge vs. total multiplicity of produced particles (open circles). Large solid circles represent the averages for samples with $n_{prod} \geq 1000$ and $Q_{\eta \geq 6} = 0, 2, 3 - 4, 5 - 7, \text{ and } \geq 8$. Large solid triangles are the calculated produced forward multiplicity $n_{\eta > 6} = Q_{\eta \geq 6} - Q_{spect}$, where Q_{spect} is the spectator charge derived from a Glauber calculation. The upper line is the fit to the data. The intercept is consistent with $Z = 82$, the charge of the beam. The lower line is fitted to the forward multiplicity points and is constrained to pass through the origin. The intersection of the two lines is an estimate of the multiplicity in events with no spectators.

FIG. 4. Densities of shower particles per wounded nucleon $dm_s/d\eta$ as a function of the pseudorapidity η . The error bars include statistical counting uncertainties in W . For each particular system, the same values of W are used to normalize the data, FRITIOF (dashed lines), and VENUS. VENUS predictions are shown with (solid lines) and without (dotted lines) reinteraction.

FIG. 5. Scaling of target and projectile regions with the number of target and projectile participants. Note that the two vertical axes are different. The target region (a) is normalized by W_T , while the projectile region (b) is normalized by W_P .

FIG. 6. Dependence of pseudorapidity density with multiplicity in three pseudorapidity intervals. The fitted lines are constrained to pass through the origin.

FIG. 7. Comparison of the charge forward of (a) $\eta = 7$ and (b) $\eta = 8$ as a function of the total produced multiplicity to a linear model.

FIG. 8. Comparison of measured peak pseudorapidity densities ($2.9 \leq \eta < 3.6$) with VENUS predictions (a) with reinteraction included, and (b) with reinteraction turned off but with all other parameters left unchanged.

FIG. 9. Derived spectator proton distribution in the Pb+Pb system. The error bars shown are statistical. Fig. 9(a) shows the distribution as a function of pseudorapidity η derived from Eq. 4; Fig. 9(b) shows the distribution transformed into angular units. In Fig. 9(b), the $\eta > 9$ data, which has large relative uncertainties in the angle, is not plotted or used in the fit.

FIG. 10. Comparison of the derived produced particle distribution as a function of pseudorapidity η with the central ($Z_b \leq 4$) sample in the spectator region.

FIG. 11. Pseudorapidity distributions of dominant charged particle species in VENUS, with (solid lines) and without (dashed lines) reinteraction.
