Allerton TD, Kowalski GM, Hang H, Stephens J. Dynamic glucose disposal is driven by reduced endogenous glucose production in response to voluntary wheel running: a stable isotope approach. Am J Physiol Endocrinol Metab 319: E2–E10, 2020. First published April 28, 2020; doi:10.1152/ajpendo.00450.2019.—To resolve both the systems level and molecular mechanisms responsible for exercise-induced improvements in glucose tolerance, we sought to test the effect of voluntary wheel running exercise on postprandial glucose dynamics. We utilized a stable isotope-labeled oral glucose tolerance test (SI-OGTT) incorporating complementary deuterium glucose tracers at a 1:1 ratio (2-2H-glucose and 6–6 2H-glucose; 2g/kg lean body mass) to distinguish between endogenous glucose production (EGP) and whole-body glucose disposal. SI-OGTT was performed in C57BL/6J mice after 8 wk on a high-fat diet (HFD; 45% fat). Mice were then randomized to either a wheel-running cage (n = 13, HFD Ex) or a normal cage (n = 13, HFD Sed) while maintaining the HFD for 4 wk before performing a SI-OGTT. HFD Ex mice demonstrated improvements in whole blood glucose total area under the curve (AUC) that was attributed primarily to a reduction in EGP AUC. Serum insulin levels measured at 0 and 15 min post-glucose gavage (AUC) that was attributed primarily to a reduction in EGP AUC. Serum insulin levels measured at 0 and 15 min post-glucose gavage were significantly elevated in the HFD Sed mice, whereas HFD Ex mice demonstrated the expected reduction in insulin at both time points. Overall, exercise improved hepatic insulin sensitivity by reducing postprandial EGP, but also increased whole-body glucose disposal. Finally, these results demonstrate the benefits of exercise on hepatic insulin sensitivity by combining a more physiological route of glucose administration (oral glucose) with the resolution of stable isotope tracers. These novel observations clearly demonstrate that SI-OGTT is a sensitive and cost-effective method to measure exercise adaptations in obese mice with as little as 2 μl of tail blood.

INTRODUCTION

Pre-diabetes and type 2 diabetes (T2D) are characterized by fasting and postprandial hyperglycemia (6). Under physiological postprandial conditions, increased blood glucose concentrations stimulate insulin secretion to reduce endogenous glucose production (EGP), enhance muscle glucose uptake, and reduce adipose tissue lipolysis in a coordinated manner to dispose of exogenous glucose and restore euglycemia. Persistent hyperglycemia, in both the fasting and postprandial state, are thought to be responsible for the increased prevalence of vascular disease in subjects with T2D (34). Notably, it appears that individuals with normal fasting glucose yet impaired glucose tolerance (IGT; pre-diabetes) already demonstrate signs of endothelial dysfunction and other diabetes related complications (1). Therefore, strategies for improving postprandial glucose metabolism are important for not only preventing the development of overt T2D but also for preventing the complications of pre-diabetes.

Exercise is an effective strategy to increase insulin sensitivity and glucose tolerance in humans and animal models of diet-induced obesity (DIO) and insulin resistance (16). Voluntary wheel running (VWR) is an exercise model (13, 14) utilized to promote common exercise-mediated skeletal muscle adaptations (i.e., mitochondrial content and function) (31). Data from exercised rats shows consistent results for improved whole body insulin sensitivity, but inconsistent benefits on tissue-specific (i.e., muscle and liver) insulin sensitivity (11, 12, 23, 30). Furthermore, while it is well known that VWR can restore glucose tolerance in DIO mice (3, 5, 41), there is little mechanistic insight into the actual metabolic pathways responsible for the improvements in postprandial glucose handling in this commonly used exercise model.

Dynamic glucose disposal is dependent on whole body coordination of insulin action and insulin secretion, which more accurately represent the transition from the fasted to fed state (43, 44). DIO mice are known to develop hyperglycemia and hyperinsulinemia and therefore present a model of insulin resistance (29, 46). The euglycemic hyperinsulinemic clamp method is a valuable tool to measure insulin action; however, it fails to replicate dynamic endogenous hormone alterations that occur during nutrient intake and may fail to elucidate undetectable metabolic phenotypes (43). Furthermore, the clamp method is an invasive procedure that does not lend itself to repeated measures over time (25). Also, the technical expertise and demands of the methodology have greatly limited its availability. Therefore, the aim of the current study was to measure glucose dynamics in a common metabolic model, DIO in C57BL/6J mice, before and after a period of VWR. We also interrogated molecular signatures of exercise-induced adaptations in skeletal muscle and liver that have been implicated in improved glucose handling.

MATERIALS AND METHODS

Animal housing and study design. The Pennington Biomedical Research Center (PBRC) Animal Care and Use Committee approved all study experiments. Four-week-old male C57BL/6J mice (n = 26) were purchased (The Jackson Laboratory, Bar Harbor, ME) and housed in the PBRC comparative biology core. Mice (4 wk old) were then multihoused (4 to a cage) and placed on a 45% high fat diet (HFD; Research Diet12451, New Brunswick, NJ) for 8 wk. Following the 8-wk HFD
feeding period, mice were individually housed and randomly allocated to either a HFD sedentary group (HFD Sed), one to a cage, with no running wheel or a cage with free access to a running wheel (HFD Ex; Minimitter, West Chester, PA) for 4 wk. Wheel revolutions were counted each minute by a magnetic switch mechanism, and data were stored using Vital View Software (version 4.0, Oakmont, PA). Body weight and food intake were measured on a weekly basis. Food intake was assessed by weighing food put in the food hopper and then weighing remaining food pellets and crumbs to determine the amount ingested (47). Body composition was measured via NMR, and a stable isotope-labeled oral glucose tolerance test (SI-OGTT) was performed to get an index of dynamic glucose disposal and pattern of endogenous glucose production both after 8 wk of HFD feeding (Pre) and again after 12 wk HFD feeding (Post; i.e., after 4 wk of exercise intervention). At the end of the experiment, mice were euthanized by isoflurane administration with cardiac puncture. A subgroup of mice \( n = 6 \), HFD Sed; \( n = 5 \), HFD Ex) from both groups was intraperitoneally injected with human insulin (Humulin, Eli Lilly, Indianapolis, IN) at a dose of 1.5 U/kg 10 min before euthanasia to examine modulation of insulin signaling proteins.

SI-OGTT. To get a readout of the dynamic changes in glucose disposal and patterns in endogenous glucose production (EGP), we employed a SI-OGTT consisting of two complementary deuterium glucose labels (2-[H]- and 6,6-[H]; Cambridge Isotope, Tewksbury, MA) at a 1:1 ratio as described previously (28). Briefly, mice were fasted for 4 h and were then gavaged with a 1:1 ratio of the glucose tracer at a total dose of 2 \( g \) lean body mass. Tail blood glucose was measured at 0, 15, 30, 60, and 120 min via gas chromatography-mass spectrometry (GS-MS). Serum [2H]-glucose concentrations were measured at 0, 15, 30, 60, and 120 min via gas chromatography-mass spectrometry (GS-MS). Serum insulin (mmol/L) was calculated by serum insulin (mmol/L) × blood glucose (mmol/L)/22.5.

The use of stable isotope-labeled glucose permits the partitioning of the blood glucose concentration into the glucose derived from endogenous (unlabeled)- and exogenous meal-derived (labeled) sources (28). A common feature of T2D in human and rodents models is hepatic futile glucose cycling (7, 27). Whereby glucose is normally phosphorylated via glucokinase and trapped in the hepatocyte by investment of energy (1 ATP), hepatic futile glucose cycling reflects the dephosphorylation of glucose by glucose-6-phosphatase and subsequent release back into the circulation. The isotopic position of [2-2H]-glucose can be recycled and positioned on glucose leaving the hepatocyte. Whereas, [6,6-2H]-glucose generally reflects glucose disposal because the \( ^{3}H \) will not be recycled back into the C-6 position (36). When provided in equimolar amounts, the dual tracer approach can detect hepatic futile glucose cycling by measuring the difference in [2-2H]-glucose area under the curve (AUC) from the AUC of [6,6-2H]-glucose (27, 28).

Preparation of tissue extracts. At the time of necropsy, adipose tissues, gastrocnemius muscle, and the liver were collected, weighed, and frozen. Triacylglycerol (TAG) were measured in serum, muscle, and liver using a colorimetric assay (Eagle Biosciences, Anherst, NH). Liver and muscle glycogen were processed by enzymatic hydrolysis and measured via a colorimetric assay (Abcam, Cambridge, MA). Serum insulin was measured by ELISA (Biovision, Milpitas, CA). The homeostatic model analysis of insulin resistance (HOMA-IR) was calculated by serum insulin (mmol/L) × blood glucose (mmol/L).

Fig. 1. Voluntary wheel running (exercise) reduces fat mass. Four-week-old C57BL/6J male mice (group-housed) were placed on a 45% high-fat diet (HFD) for 8 wk. Mice were randomized and single housed in sedentary (Sed) or wheel running (Ex; bar with hashed lines) conditions for an additional 4 wk (12 wk total). Body weight was measured weekly over the 12-wk experiment (A) as was food intake (B). NMR was utilized to measure body fat percentage (C), lean mass (D), and body fluid (E). F: adipose tissue mass weights for inguinal (iWAT), epididymal (eWAT), mesenteric (mWAT), and retroperitoneal (rWAT) white adipose tissue. E: time effect refers to difference between pre- and postmeasurements. Activity effect refers to difference between Sed and Ex mice. Time × activity indicates an interaction. All data are expressed as means ± SE. ***P < 0.001, ****P < 0.0001; n = 13/group.
Glucose tolerance. To assess glucose dynamics, we performed an OGTT with two stable isotopes (SI). The SI-OGTT can distinguish between exogenous glucose and endogenous sources of glucose. A typical OGTT is shown in Fig. 2A, where glucose measurements were assessed with a glucometer and represents both labeled and unlabeled glucose. As shown in Fig. 2B, whole blood glucose AUC following the SI-OGTT was not different between the HFD Sed and HFD Ex before randomization at 8 wk (Pre). However, following the 4-wk VWR intervention, exercised mice had a significant reduction in the glucose AUC compared with the sedentary controls. Serum insulin measured at time 0 and 15 min after glucose gavage did not differ between groups before randomization (Fig. 2C). Yet, insulin levels were reduced in the HFD exercised mice compared with sedentary conditions (Fig. 2C). Serum NEFA levels were not different between the sedentary and exercised groups both pre- and postintervention (Fig. 2D). As expected, HOMA-IR was significantly (P < 0.001) reduced in the exercised group (Fig. 2E).

SI-OGTT. The utilization of complementary stable isotope tracers 2-[2H]-glucose and 6,6-[2H]-glucose allows for the ability to separate administered glucose (labeled glucose) vs. endogenous glucose (unlabeled glucose) and provides an index of the suppression of endogenous glucose production (EGP) and dynamic glucose disposal. Before randomization (Pre), there were no differences for endogenous glucose, 2-[2H]-glucose and 6,6-[2H]-glucose AUC between the two groups of mice (Fig. 3, A–C). However, HFD exercised mice had a reduction in endogenous glucose AUC (Pre vs. Post) and between groups of mice (exercised vs. sedentary). After conducting a repeated measures two-way ANOVA, we detected significantly lower endogenous glucose levels at the 0-, 60-, and 120-min time points for the glycemic fluctuations (Fig.
The shape of the endogenous glucose excursion curve where it dips between 15 and 30 min post-glucose gavage coincides with the progressive increase in exogenous, isotopically labeled glucose. This is also the period when insulin secretion increases (Fig. 2C), demonstrating the capacity, albeit low, for insulin to suppress hepatic glucose release. There were no significant differences between groups in the measurement of 2-[2H]-glucose and 6,6-[2H]-glucose AUC and glycemic fluctuations (Fig. 3, A and D, 2-[2H]-glucose (B and E), 6,6-[2H] glucose (C and F) concentrations, and hepatic futile cycle (G) were measured during the stable isotope-labeled oral glucose tolerance test (SI-OGTT) at Pre (week 8) and Post (week 12). Time effect refers to difference between pre- and post-measurements. Activity effect refers to the difference between Sed and Ex mice. Time x activity indicates an interaction. All data are expressed as means ± SE. *P < 0.01, **P < 0.001, ***P < 0.001, #P < 0.01, ##P < 0.001, within-group effect; n = 13/group.

Serum and tissue triglycerides and glycogen. VWR results in a significant reduction in triacylglycerol (TAG) levels in serum (Fig. 4A) and the liver (Fig. 4B) compared with sedentary controls. Conversely, muscle TAG levels were increased, but not significant, in HFD Ex vs. Sed mice (Fig. 4C). Notably, there was a compelling trend for a reduction in liver glycogen content (P < 0.057) in exercised mice compared with sedentary controls. However, there were no differences detected in skeletal muscle (mixed gastrocnemius muscle) glycogen content between the two groups (Fig. 4E).

**Protein abundance and gene expression.** Ten minutes before euthanasia, mice in each were group were injected with vehicle (HFD Sed, n = 7; HFD Ex, n = 8) or insulin (HFD Sed, n = 6; HFD Ex, n = 5). Insulin sensitivity was assessed in skeletal muscle (gastrocnemius) and the liver by examining acute insulin induction of Akt phosphorylation. As shown in Fig. 5A, there was a significant in both HFD Sed mice (P = 0.002) and HFD Ex mice (P = 0.01) increase in phosphorylation of Akt (AktS473) following acute insulin treatment. Insulin induction of liver Akt phosphorylation was significantly increased in HFD Ex mice (P = 0.05), but not HFD Sed mice (P = 0.80)
Fig. 4. Muscle glycogen is increased, while liver glycogen is decreased in response to voluntary wheel running. Serum triglycerides (TAG), muscle, and liver extracts were measured for TAG and glycogen after 4 wk. The effect of 4 wk of exercise on serum (A), liver (B and D), and muscle (C and E) TAG and glycogen content. All data are expressed as means ± SE. *P < 0.01, ***P < 0.001; n = 8/group.

(Fig. 5C). Basal phosphorylation of AMPK (AMPKThr172) in skeletal muscle was significantly elevated in HFD Ex mice (P = 0.002) compared with HFD Sed mice (Fig. 5B). There was no difference in liver pAMPK between groups (P = HFD Sed vs. HFD Ex, P = 0.18) (Fig. 5D). Muscle PDK4 protein abundance tended to be increased in exercised mice, but did not reach statistical significance (P = 0.09) (Fig. 5B). Liver PDK4 levels were not significantly different between the groups (P = 0.29) (Fig. 5D). PDK4 migrates at 42 kDa, indicated by the arrow in the figure, but we did find a nonspecific band at 38 kDa in both gastrocnemius and liver samples (Fig. 5, B and D). STAT5B expression was used as a loading control. These muscle and liver samples were also used for gene expression analysis (Fig. 6). The mRNA levels of endothelial nitric oxide synthase (eNOS; P < 0.05), malate dehydrogenase 1 (mdh1; P < 0.0001), and citrate synthase (CS; P < 0.001) were significantly increased in mixed gastrocnemius muscle. In the liver, there was a notable increase in FOXO1 (P < 0.001) and a decrease in Pdk4 mRNA levels in exercised mice compared with sedentary controls.

Fig. 5. Effect of voluntary wheel running on expression of insulin signaling proteins in skeletal muscle and liver. Whole tissue extracts were subjected to immunoblotting [mixed gastrocnemius (Gastroc) and liver] to detect changes in total levels of PDK4 and in the ratio of phosphorylated Akt to Akt (AktSer473/Akt; insulin injection) and basal AMPK phosphorylation at threonine 172 to total AMPK (pAMPK/AMPK). Five to six samples per group are shown in representative images, for pAkt/Akt and n = 6 – insulin/n = 6 + insulin for high-fat diet (HFD) sedentary (Sed) and n = 6 – insulin/n = 5 + insulin for HFD wheel running (Ex) mice. For pAMPK/AMPK and PDK4, n = 6 for both groups were used for quantification of band intensity shown in the graphs to the right of blots. STAT5B and α-tubulin were used as loading controls. Data for Akt are expressed as a ratio and AMPK and PDK as fold-change (*P < 0.01, **P < 0.001).
Liver

Fig. 6. Exercise decreases PDK4 and increases FOXO1 gene expression in liver, but not muscle, in high fat-fed (HFD) mice. Total RNA was isolated from mixed gastrocnemius (Gastroc) and liver tissues. Total RNA was isolated from frozen tissue samples and subjected to RT-qPCR to examine a panel of genes involved in gluconeogenesis, metabolic flexibility, and mitochondrial function. All data are expressed as fold-change vs. sedentary controls (Sed CTLs) ± SE. *p < 0.01, **p < 0.001, ***p < 0.0001, ****p < 0.00001; n = 8/group.

**DISCUSSION**

Regular aerobic exercise improves muscle glucose uptake and insulin sensitivity in humans with T2D (16, 45). In rodent models of DIO, consumption of a HFD and the accompanying increase in adiposity leads to an insulin-resistant/glucose-intolerant state (46). VWR is commonly utilized to replicate exercising training due its unforced nature and propensity for muscle glycogen content (9, 39). Interestingly, after 4 wk of wheel running, exercised mice did not have significant alterations in muscle glycogen levels; however, there was a strong trend (P = 0.057) for lower liver glycogen content (Fig. 4D). Our observations are consistent with other studies showing that VWR reduces liver glycogen content in a dose-dependent (volume of daily wheel running per day) manner (10). The exercise mice in our study did demonstrate a significant improvement in insulin sensitivity as evaluated by HOMA-IR (Fig. 2E). Since HOMA-IR incorporates fasted blood glucose and insulin levels, these observations also support an improvement in hepatic glucose metabolism, but not necessarily alterations in dynamic glucose disposal. Mice engaging in wheel running or forced treadmill running do not require muscle glycogen, but can maintain energy needs through gluconeogenesis and glycogenolysis in the liver (37). After exhaustive exercise, muscle glycogen levels are replenished preferentially upon refeeding after exercise (9). However, in our exercise model, VWR likely

with sedentary controls (Fig. 1A). The reduction in body weight was accompanied by a reduction in the percentage body fat between the sedentary and exercised mice (Fig. 1C). Also, percent lean body mass was higher in exercised mice after 1 mo but did not differ compared with absolute lean mass (Fig. 1D). We did not measure any significant differences in food intake (Fig. 1B) between the two groups over the course of the study. Hence, the increased energy expenditure that occurs with VWR without a compensatory increase in food intake likely explains the overall differences we observed in body mass and composition.

Despite apparent fasting and postprandial hyperinsulinemia (Fig. 2A), sedentary mice had both increased fasting and OGTT blood glucose levels compared with the exercised group. The major advantage of using the SI-OGTT is that it permits the blood glucose concentration to be partitioned into what is derived from exogenous (oral glucose) and endogenous (produced by liver and kidneys) sources, permitting an index of glucose disposal and pattern of EGP to be estimated. 2-[3H]-glucose is subjected to hepatic futile cycling, whereas 6,6-[2H]-glucose is not. Therefore, we were able to measure glucose disposal and hepatic futile cycling. We did not detect a large degree of hepatic futile cycling in sedentary or exercised mice (Fig. 3G). This is consistent with previous reports showing long duration (42 wk) feeding of a HFD, high-sucrose diet was necessary to induce hepatic futile cycling (28, 29). It is possible that the 45% HFD used in the current study is not a sufficient metabolic challenge to induce a loss of hepatic efficiency. Therefore, future implementation of this aspect of the SI-OGTT may be more appropriate for animals undergoing more severe metabolic challenges for longer periods of time. For comparison of glucose disposal and endogenous glucose, the sole use of 6,6-[2H]-glucose, without 2-[3H]-glucose, will provide valuable information in less severe models of insulin resistance.

Acute and chronic exercise improve insulin sensitivity in both human and animal models (10, 16, 39). Improved insulin sensitivity in the immediate and extended time period after exercise (3–4 h) is thought to be linked to reduced skeletal muscle glycogen content (9, 39). Chronic exercise adaptations are thought to occur via more effective intracellular insulin signaling and improved mitochondrial capacity to oxidize lipids, thereby reducing substrate competition in skeletal muscle (4, 17, 25). Interestingly, after 4 wk of wheel running, exercised mice did not have significant alterations in muscle glycogen levels; however, there was a strong trend (P = 0.057) for lower liver glycogen content (Fig. 4D). Our observations are consistent with other studies showing that VWR reduced liver glycogen content in a dose-dependent (volume of daily wheel running per day) manner (10). The exercise mice in our study did demonstrate a significant improvement in insulin sensitivity as evaluated by HOMA-IR (Fig. 2E). Since HOMA-IR incorporates fasted blood glucose and insulin levels, these observations also support an improvement in hepatic glucose metabolism, but not necessarily alterations in dynamic glucose disposal. Mice engaging in wheel running or forced treadmill running do not require muscle glycogen, but can maintain energy needs through gluconeogenesis and glycogenolysis in the liver (37). After exhaustive exercise, muscle glycogen levels are replenished preferentially upon refeeding after exercise (9). However, in our exercise model, VWR likely
did not promote exhaustion. Low-, moderate-, and high-dose insulin tolerance testing may provide unique insight into tissue-specific adaptations to VWR.

Importantly, liver and serum TAG levels were markedly reduced in exercised mice while muscle levels were not significantly different (Fig. 4), findings that have previously been reported in 4-wk exercise-trained HFD-fed mice (20). During acute exercise, C57BL/6J mice increase hepatic glucose production to maintain glycemia via increased glycogenolysis and gluconeogenesis (17). Considering the similar trends in glucose tracer (6,6-2\(^{13}\)C glucose) disposal and the differential pattern of endogenous glucose levels during the OGTT between the sedentary and exercised mice, these data suggest that adaptations in the liver may explain the improvement in glycemia that occur with VWR.

In our studies, muscle insulin signaling was significantly increased in both sedentary and exercised mice, but not the increase in insulin-mediated phosphorylation ofAkt was not greater in the HFD Ex mice. This observation is not surprising in a consideration of evidence that phosphorylation ofAkt is not necessary for exercise-induced improvements in insulin sensitivity (8). However, we did detect a significant increase in hepatic insulin-mediated Akt phosphorylation in HFD Ex mice compared with HFD Sed mice. Our in vivo SI-OGTT also supports an improved hepatic response to glucose and insulin for HFD Ex mice. Additionally, hepatic FOXO1 mRNA levels were elevated in the exercised group, suggesting that at least some aspect of gluconeogenesis was altered due to wheel running.

There were discrepancies between pAMPK levels in skeletal muscle and liver protein levels (Fig. 5). Exercise increased pAMPK levels significantly, but not in the liver (HFD Ex vs. HFD Sed). This observation is somewhat expected in the consideration of data that show that forced treadmill exercise in the fasted state was required to increase muscle and hepatic AMP levels (2). However, this result could also be considered somewhat unexpected given the near significant reduction in hepatic glycogen content measured in exercised mice (Fig. 4D). Overall, these observations may reflect the adapted state to lower hepatic glycogen content rather than acute activation ofAMPK via increased AMP accumulation. The increase in skeletal muscle phosphorylation ofAMPK would suggest smaller perturbation in the energetic state can sufficiently activate this pathway.

PDK4 is a negative regulator of the PDH complex and reduces pyruvate flux into the mitochondria to favor fatty acid oxidation (4). Skeletal muscle PDK4 protein levels tended to be increased in HFD Ex mice, which likely corresponds to a greater shift toward fat oxidation. Interestingly, while protein content in the liver for PDK4 was not different between sedentary and exercised groups, PDK4 mRNA levels were significantly reduced in exercised mice (Fig. 6). These data demonstrate the known differential responses to exercise between skeletal muscle and the liver (15, 19, 24, 38, 40). Increased PKD4 in the skeletal muscle likely promotes the glycogen synthetase response by preserving gluconeogenic substrates derived from pyruvate (15). Whereas reduced PDK4 mRNA levels in the liver are associated with the promotion of glucose oxidation (38). Similarly, genetic inactivation of liver PKD4 markedly improves hepatic insulin resistance and reduces hepatic glucose production, suggesting that control of hepatic PKD4 expression plays a role in mediating the metabolic effects of exercise (35, 42).

After oral glucose ingestion, glucose disposal is shared primarily between the skeletal muscle and the liver (~30% for both tissues) (18, 22, 36). Oral glucose tolerance testing provides a physiological route for glucose to promote insulin secretion; however, factors such as EGP and glucose disposal remain unknown. The improved efficiency of liver glucose uptake and suppression of glucose output is not often considered in the adaptations to exercise training. The startling worldwide upsurge in fatty liver diseases emphasizes the importance of exploring hepatic adaptations to exercise training. To our knowledge, this is the first report to demonstrate postprandial glucose dynamics using stable isotope tracers in exercising high-fat-fed mice influenced by reduced fasting glucose and lower endogenous glucose excursion in response to VWR. Overall, these observations expand our knowledge of the physiological adaptations that occur in this well-studied mouse model of metabolic disease.
