The adiabatic temperature changes (ΔTad) in the vicinity of the Curie and martensitic transition temperatures of Ni50Mn35In15 and Ni50Mn35In14Z (Z=Al and Ge) Heusler alloys have been studied using an adiabatic magnetocalorimeter of 250–350 K temperature interval for applied magnetic field changes up to ΔH=1.8 T. The largest measured changes were ΔTad=−2 and 2 K near the martensitic (first-order) and ferromagnetic (second-order) transitions for ΔH=1.8 T, respectively. It was observed that |ΔTad|=1 K for relatively small field changes (ΔH=1 T) for both types of transitions. The results indicate that these materials should be further explored as potential working materials in magnetic refrigeration applications. © 2011 American Institute of Physics. [doi:10.1063/1.3574088]

The magnetic materials that exhibit large magnetocaloric effects (MCEs), i.e., the ability to absorb or produce heat as the result of the application of external magnetic fields (H), are of significant interest because of their potential impact for application in environmentally friendly refrigeration devices.1 The MCE originates from the change in magnetization induced by the magnetic field, and characterized by a change in magnetic entropy and, therefore, in the temperature of the sample. Magnetic systems that undergo field-induced phase transitions, characterized by large, sharp changes in magnetization near or above room temperature, are of considerable interest as promising MCE materials. One such system is the off-stoichiometric Ni50Mn50−xInx Heusler alloys. It has been found that these compounds, with concentrations in vicinity of x=15, demonstrate a specific type of structural instability known as a martensitic transformation. This instability is described as a temperature-induced first-order structural phase transition (at TM) from a high-temperature austenitic phase (AP) with cubic L21 or B2 crystal structure, to a low-temperature martensitic phase (MP) (or inverse transition at TM), characterized by a crystal cell of lower symmetry (tetragonal, tetragonal modulated, orthorhombic, or monoclinic).2 In most cases, the AP is ferromagnetically ordered below TC, and TC is greater than TA and TM. At least four magnetic phases can be detected in the compounds; (i) a low temperature ferromagnetic MP (below TCM), (ii) an antiferromagnetic/paramagnetic MP (TCM<T< TM), (iii) a ferromagnetic AP (TM<T<TC), and (iv) a high temperature paramagnetic AP (TC<T) [see, for example, Ref. 3, and references therein].

The off-stoichiometric Ni–Mn–In Heusler alloys exhibit a magnetostructural, field-induced metamagnetism at H=HM, exchange bias, nonreciprocal effects in magnetization, large MCEs, and so on (see Refs. 2–6, and references therein). Large negative (normal) and positive magnetic entropy changes, attributed to the first-order transition (FOT) and second-order transition (SOT), have been observed in these materials near room temperature.2–4 The presence of both “normal” and “inverse” magnetic entropy changes near room temperature in the Heusler alloys (sometimes in the same material), has spurred the development of a refrigeration cycle that exploits both types of effects.7,8 It was reported that the ΔSM and net refrigeration capacity, (after accounting for hysteresis loss) of Ni50Mn50In15 in the vicinity of the FOT and SOT were, respectively, 35 J kg−1 K−1, 57 J/kg and −5.7 J kg−1 K−1, 123 J/kg for ΔH=5 T.9 It has been also shown that the MCE of the In-based Heusler alloys are extremely sensitive to elemental substitution and stoichiometric variations. One example is the Si-doped Ni–Mn–In system, Ni50Mn35In15−xSi1 (1≤x≤5). In this case, it was found that the Si doping resulted in a 300% enhancement (for x=3) of the maximum inverse magnetic entropy change to a value of ΔSM=(+1)124 J K−1 kg−1 for a field change of 5 T. The normal (negative) magnetic entropy change that occurs at the SOT spans a large temperature range (240–290 K).3,8,10 The adiabatic change in temperature, ΔTad, has been studied for off-stoichiometric Heusler alloys in Refs. 11–13. It was found that ΔTad at TM is about −3 K for ΔH=50 kOe for Ni50Mn35In16 and Ni50Mn35In12Ge2. The ΔTad =−0.01 and 0.02 K for ΔH=1 T has been reported in vicinity of TM and TC, respectively, for MnxNi50In10.11 However, most studies have concentrated on the term evaluation from isothermal magnetizations measurements. Therefore, the search for materials that show a large increase in field-induced adiabatic temperature changes in the vicinity of first- and second-order phase transitions at relatively low fields is important from an application perspective.

In this letter, we report the results of direct (magnetocalorimetric) measurements of ΔTad in vicinity of the phase transitions of Ni50Mn35In15 and Ni50Mn35In14Z (Z=Al and Ge) for applied magnetic field changes up to 1.8 T. The maximum ΔTad of about −2 and 2 K were found for FOT and SOT at ΔH=1.8 T, respectively, for all samples under investigation. It was observed that the presence of Z atoms

Ferromagnetic type magnetization curves were observed in Ni<sub>50</sub>Mn<sub>35</sub>In<sub>15</sub>, Ni<sub>50</sub>Mn<sub>35</sub>In<sub>14</sub>Al, and Ni<sub>50</sub>Mn<sub>35</sub>In<sub>14</sub>Ge. The external magnetic fields have been ramped at a temperature range of 250–350 K, and in magnetic fields up to 1.8 T. All measurements were carried out during heating after the samples were cooled from 400 to 80 K at zero magnetic field that correspond to the zero field cooled (ZFC) magnetization in the low-temperature region (T < T<sub>CM</sub>) is typical for many Ni–Mn–In based compounds, and is related to the magnetic heterogeneity that can result in exchange bias effects. 3, 9

Negative and positive changes in sample temperature were found, as expected, in the presence of external magnetic fields in the vicinity of the FOT and SOT, respectively (see Fig. 3). The magnitudes of ΔT<sub>ad</sub> were found to be nearly similar (but opposite in sign) at both transitions. This behavior may be related to the similar nature of the transitions; a ferromagnetic to paramagnetic transition at T<sub>C</sub>, and an inverse of that transition at T<sub>M</sub>. The maxima of ΔT<sub>ad</sub> are a linear function of applied field for the SOT but only slightly change at low magnetic fields (0.3–1.0 T) for the FOT [see inset of Fig. 3(a)] and increase nonlinearly at H > 1.0 T. The maxima of ΔT<sub>ad</sub> are slightly smaller (by about 20%) for Ni<sub>50</sub>Mn<sub>35</sub>In<sub>14</sub>Ge (compared to the other alloys) for both transitions. The FOT and SOT temperature ranges for this compound nearly overlap (see Fig. 2), and the ferromagnetic ordering in the AP is incomplete. Thus the magnetization of Ni<sub>50</sub>Mn<sub>35</sub>In<sub>14</sub>Ge above T<sub>M</sub> is smaller than that observed for Ni<sub>50</sub>Mn<sub>35</sub>In<sub>14</sub>Al and Ni<sub>50</sub>Mn<sub>35</sub>In<sub>15</sub> (see Fig. 2), and this difference in magnetic order results in a decrease in ΔT<sub>ad</sub>.

The MCE at low magnetic fields is of particular importance from an application point of view. As one can see from Fig. 3(d), the changes in the sample temperatures remain rather large (about 1 K) for both transitions for a relatively small magnetic field change of 1.0 T. The relative cooling power (RCP), based on the adiabatic temperature change, has been estimated as RCP(T)=ΔT<sub>ad</sub>(T)/H × dHFWHM. 14 |RCP|=23 K<sup>2</sup>/T and 6 K<sup>2</sup>/T, for Ni<sub>50</sub>Mn<sub>35</sub>In<sub>15</sub>; 24 K<sup>2</sup>/T and 7 K<sup>2</sup>/T, for Ni<sub>50</sub>Mn<sub>35</sub>In<sub>14</sub>Al; and 5 K<sup>2</sup>/T and 2 K<sup>2</sup>/T, for Ni<sub>50</sub>Mn<sub>35</sub>In<sub>14</sub>Ge as calculated in vicinity of T<sub>C</sub> and T<sub>M</sub>, respectively, for ΔH=1 T, and Ref. 14.

The maxima of ΔT<sub>ad</sub> at the SOT are shifted to lower and higher temperature regions for Ni<sub>50</sub>Mn<sub>35</sub>In<sub>14</sub>Ge and Ni<sub>50</sub>Mn<sub>35</sub>In<sub>14</sub>Al, respectively, compared to the parent compound. The temperature of the maximum of ΔT<sub>ad</sub> at the FOT increases from 298 to 309 K for Ni<sub>50</sub>Mn<sub>35</sub>In<sub>15</sub>, following the changes in T<sub>M</sub>. The observed results are in agreement with the estimation of ΔT<sub>ad</sub> obtained in Ref. 15 from magnetization and specific heat capacity measurements of

![Fig. 1. Room temperature XRD patterns of Ni<sub>50</sub>Mn<sub>35</sub>In<sub>15</sub>, Ni<sub>50</sub>Mn<sub>35</sub>In<sub>14</sub>Al, and Ni<sub>50</sub>Mn<sub>35</sub>In<sub>14</sub>Ge.](Image)

![Fig. 2. (Color online) ZFC magnetization curves M(T) for Ni<sub>50</sub>Mn<sub>35</sub>In<sub>15</sub>, Ni<sub>50</sub>Mn<sub>35</sub>In<sub>14</sub>Al, and Ni<sub>50</sub>Mn<sub>35</sub>In<sub>14</sub>Ge.](Image)
Ni$_{50}$Co$_{2}$Mn$_{35}$In$_{15}$. The $\Delta T_{ad}$ observed for Ni$_{50}$Mn$_{35}$In$_{15}$ and Ni$_{50}$Mn$_{35}$In$_{14}$Al are larger than those reported for Ni$_{50}$Mn$_{35}$In$_{16}$ in Refs. 11–13. This can be explained as a result of the difference in the magnetic states of these compounds just below their respective martensitic transition temperatures.

It is necessary to emphasize here that $\Delta T_{ad}$ is approximately the same magnitude at the FOT and SOT. However, $\Delta T_{ad}$ is free of hysteresis at the SOT, and there is no time dependence of $\Delta T_{ad}$ at the SOT [at least on the timescale of the most important applications, which typically operate at 1–10 Hz (Ref. 1)]. Our direct measurements of $\Delta T_{ad}$ with the rate of changing magnetic field of 0.05–2.0 T/s did not reveal any time dependence of $\Delta T_{ad}$ at the SOT. In comparison with Gd, which is (according Ref. 1) the most effective near room temperature, the Ni$_{50}$Mn$_{35}$In$_{14}$Z (Z=In, Al, and Ge) Heusler alloys exhibit approximately the same MCE properties in vicinity of the SOT but they are much cheaper and do not contain chemically active components.

Using a magnetocalorimeter, we have directly measured the adiabatic temperature changes ($\Delta T_{ad}$) of three Ni–Mn–In based Heusler alloys near their respective FOT (martensitic) and SOT (ferromagnetic). At the SOT, the magnitudes of $\Delta T_{ad}$ for these materials are a nearly linear function of applied field, whereas $\Delta T_{ad}$ at the FOT slightly changes at $H=0.3$–1.0 T. The largest negative $\Delta T_{ad}$ was observed in Ni$_{50}$Mn$_{35}$In$_{15}$ to be about $-2$ K at the martensitic transformation for a field change of 1.8 T. The adiabatic temperature changes in about 1 K have been revealed for both, FOT and SOT, at a relatively small magnetic field change of 1 T for all of the studied compounds. The temperatures of the maxima of $\Delta T_{ad}$ were found to be tunable in the quaternary alloys Ni$_{50}$Mn$_{35}$In$_{14}$Z by substituting 1% of Z=Al and Ge; the maxima could be shifted up to 11 K relative to the parent compound. These results, and the implied potential impact on magnetic refrigeration applications, provide an impetus for further research on these systems.
