I. INTRODUCTION

Does quantum mechanics play a nontrivial role in evolutionary or molecular processes in biological systems? How could this result be true, when biological systems interact in environments that are “hot” and “wet”? Furthermore, how can we frame the first question rigorously? These questions have been the subject of intense debate [1, 2] and a surge of recent interest from both the quantum information community [3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16] and the experimental quantum chemistry community [17, 18, 19, 20]. This active area is sometimes described as “quantum biology” [2, 11]. Some have suggested that, in addition to the possibility of remarkable new insights into biology, there is the potential to harness naturally occurring coherent quantum effects in biology to engineer new devices.

Two biological processes are playing a particularly important role in fueling interest in this subject: energetic excitation transfer in the Fenna-Matthews-Olson (FMO) light-harvesting protein complex of green bacteria [3, 4, 12, 13, 14, 15, 16, 17, 18, 20, 21, 22, 23, 24, 25, 26, 27, 28] and the radical ion-pair mechanism in the so-called avian compass [3, 8, 14, 16, 17, 18, 28] and the radical ion-pair mechanism in the so-called avian compass. [3, 8, 14, 16, 17, 18, 28]. For each system, there are claims of quantum mechanical behavior in the scientific literature. On the theory side, several studies in the literature have proposed an open quantum systems approach to model the dynamics of these biological processes [3, 14, 17] and have lent credence to the proposition that coherent quantum effects play a role in their functionality.

Agreement between quantum theoretical models and experiment, however, does not irrevocably demonstrate the presence of quantum effects. This point is subtle, but it is a logical fallacy, called the “affirmation of the consequent,” to conclude once and for all that the quantum biological models are the correct models simply because they coincide with the observations of some experiments (Leggett stresses this point in several of his papers [29, 30]). It would be useful to irrevocably exclude certain classes of classical models that might apply to these biological systems by considering fundamental tests of non-classicality.

One might wonder if it is well-motivated to conduct a test for non-classicality on a system such as the FMO complex that is clearly microscopic. In fact, is it not obvious that the FMO complex should behave according to quantum-mechanical laws, given that the length scales and time scales are those to which quantum theory applies? We argue that applying a test for non-classicality is valuable here because a significant amount of environmental noise acts on the chromophores of the FMO complex. These decohering effects may “wash out” quantum-mechanical behavior and make it appear as if the FMO complex behaves according to a class of macro-realistic models (after all, some argue that classical behavior in general arises due to such decoherence [31]). In some cases (in a high temperature limit), researchers actually have modeled the dynamics of the FMO complex with a classical incoherent hopping (Förster) model [21, 22, 32, 33]. Recent results [3, 14, 17] suggest that a classical incoherent hopping model is insufficient to explain the ultra-efficient transfer of energy in photosynthesis, but a test for non-classicality could irrevocably exclude the whole class of models to which the classical incoherent hopping model belongs.

In this paper, we frame a test for non-classicality in the FMO protein complex, the molecular complex responsible for the transfer of energetic excitations in a photosynthetic reaction. Quantum chemists have deter-
determined a tight-binding Hamiltonian for this simple system \[24\]. Phenomenological modifications to the standard Schrödinger equation have allowed an open quantum systems model of its dynamics \[3, 4, 12, 13\]. Motivated by experimental results, several theoretical studies have computed the efficiency of energy transfer from the chlorosome antenna to the reaction center in green bacteria and have asserted that coherent quantum effects play a role. To assess this claim, we frame a test for violation of macrorealism, as quantified by the Leggett-Garg inequality \[34\]. In this sense, we are following the program of Leggett outlined in Ref. \[29\] and the suggestion of Zeilinger in Ref. \[1\] that it would be useful to subject biomolecules to tests of non-classicality. The Bell \[35, 36\] and Leggett-Garg \[33\] tests of non-classicality are benchmarks that determine whether a given dynamical system has stronger-than-classical spatial or temporal correlations, respectively. Each of these tests provides an inequality that bounds the spatial or temporal correlations of a given system—a violation of the inequality implies that the system in question does not behave in a classical manner. The advantage of the Leggett-Garg test over a Bell test is that a Leggett-Garg test applies to a single quantum system, easing experimental difficulty. The Leggett-Garg inequality was originally applied to superconducting quantum systems. It was later considered for other systems such as quantum dots \[37, 38, 39\] and photons \[40\] but, to our knowledge, this is the first application of Leggett and Garg \[34\]. Let \(C_{i,j}\) denote the following two-time correlation function:

\[
C_{i,j} \equiv \langle Q(t_1)Q(t_2) \rangle .
\]

The Leggett-Garg quantity \(K\) is the following combination of three two-time correlations and a constant:

\[
K \equiv C_{1,2} + C_{2,3} + C_{1,3} + 1 .
\]  

Note that we can obtain the alternate Leggett-Garg quantities

\[
\begin{align*}
- C_{1,2} + C_{2,3} - C_{1,3} + 1, \\
- C_{1,2} - C_{2,3} + C_{1,3} + 1, \\
C_{1,2} - C_{2,3} - C_{1,3} + 1,
\end{align*}
\]

merely by flipping the sign of the respective observables \(Q(t_1), Q(t_2),\) and \(Q(t_3)\). The following Leggett-Garg inequality bounds the Leggett-Garg quantity \(K\) when the system in question is a macrorealistic system being measured noninvasively:

\[
K \geq 0 .
\]  

The last correlation function \(C_{1,3}\) is to be obtained experimentally by measuring at times \(t_1\) and \(t_3\) but refraining from measuring at time \(t_2\). By comparing \(C_{1,3}\) to correlation functions \(C_{1,2}\) and \(C_{2,3}\) obtained in the presence of a measurement at \(t_2\), the Leggett-Garg inequality is sensitive to invasiveness in the \(t_2\) measurement.

An example of a system that violates the Leggett-Garg inequality is a spin-1/2 particle with system Hamiltonian \(H = \omega \sigma_X / 2\) and with the observables \(Q(t_1) = Q(t_2) = Q(t_3) = \sigma_Z\). This choice leads to the following value of the Leggett-Garg quantity \(K\) in \([1]\):

\[
K = \cos(2\omega \Delta t) + 2 \cos(\omega \Delta t) + 1 ,
\]

where the parameter \(\Delta t\) is the uniform time interval between the successive measurements of the observable.

II. THE LEGGETT-GARG INEQUALITY

The Leggett-Garg inequality applies to any system that obeys the postulates of macrorealism. The postulates of macrorealism for a two-level system are as follows \[29, 34\]:

1. **Macrorealism per se**: A macroscopic object is in one of two definite states at any given time.

2. **Noninvasive measurement**: It is possible in principle to determine the state of the system without affecting it or any subsequent dynamics.

3. **Induction**: The properties of ensembles are determined exclusively by initial conditions (and, in particular, not by final conditions).

It is reasonable to assume that a classical system, in principle, should obey the postulates of a macrorealistic theory.

The Leggett-Garg inequality bounds the two-time correlation functions of three dichotomic observables \(Q(t_1), Q(t_2),\) and \(Q(t_3)\) measured at respective times \(t_1, t_2,\) and \(t_3\). The observables \(Q(t_1), Q(t_2),\) and \(Q(t_3)\) could be the spin of a particle or the location of the trapped magnetic flux in a double-well potential as in the original application of Leggett and Garg \[34\]. Let \(C_{i,j}\) denote the following two-time correlation function:

\[
C_{i,j} \equiv \langle Q(t_1)Q(t_2) \rangle .
\]
Observe that choosing the interval $\Delta t = 3\pi/4\omega$ sets $K = -\sqrt{2} + 1$ and leads to a violation of the Leggett-Garg inequality in [5]. Thus, this quantum system does not obey the postulates of a macrorealistic theory when we choose the measurement time intervals as given above. This violation is perhaps not surprising because a spin-1/2 system is a genuine quantum system and “cannot have the objective properties tentatively attributed to macroscopic objects prior to and independent of measurements” [41].

III. MODEL FOR THE FMO COMPLEX

Much of the “quantum biological” interest has focused on energy transport in the Fenna-Matthews-Olson (FMO) protein complex [23], which is the main contributor to ultra-efficient energy transfer in photosynthesis. The FMO protein complex is a trimer in the bacterial species *prosthecochloris aestuarii*. The theoretical models in the literature [3, 4, 12, 13, 16] apply to the dynamics of one unit of the trimer. The model assumes that a photon impinges on the peripheral antenna of the light harvesting complex. Absorption of the photon produces an electronic excitation, an exciton, that then traverses a network of seven chromophores or sites in one unit of the trimer. The exciton can either recombine, representing a loss of the excitation, or it can transfer to a reaction center, where a light-to-charge conversion occurs before energy storage. Theoretical models [12, 13] indicate that coherent quantum effects combined with decoherence may lead to a quantum stochastic walk [12] that transports energy efficiently. Rebertost et al. provide evidence that coherent quantum effects are responsible for the ultra-high efficiency of photosynthesis [13] by demonstrating that the transport efficiency is much higher with coherent quantum effects than it is without.

Our physical model for excitation transfer is the nine-level model in Refs. [3, 4, 12, 13, 16]. We can restrict dynamics to the single-excitation manifold because the excitation number is a conserved quantity in the absence of light-matter interaction events (within the exciton recombination time scale of 1 ns [41]). The possible states for the exciton can be expressed in the site basis $\{|m\rangle\}_{m=1}^{7}$, where the state $|m\rangle$ indicates that the excitation is present at site $m$. The incoherent dynamics include a “ground” state $|G\rangle$ corresponding to the loss or recombination of the excitation and a sink state $|S\rangle$ corresponding to the trapping of the exciton at the reaction center. The excitation evolves into one of the two states $|G\rangle$ or $|S\rangle$ in the limit of infinite time. The density operator $\rho$ for this open quantum system admits the following representation in the site basis:

$$\rho = \sum_{m,n\in\{G,1,\ldots,7\}} \rho_{m,n} |m\rangle \langle n|.$$  

We simplify our analysis by assuming that the dynamics of the density operator are Markovian. Thus, a Lindblad master equation, with coherent and incoherent components, models the dynamics [15, 16]. Coherent evolution occurs according to the following Hamiltonian $H$ [24]:

$$H \equiv \begin{bmatrix} 215 & -104.1 & 5.1 & -4.3 & 4.7 & -15.1 & -7.8 \\ -104.1 & 220 & 32.6 & 7.1 & 5.4 & 8.3 & 0.8 \\ 5.1 & 32.6 & 0 & -46.8 & 1.0 & -8.1 & 5.1 \\ -4.3 & 7.1 & -46.8 & 125 & -70.7 & -14.7 & -61.5 \\ 4.7 & 5.4 & 1.0 & -70.7 & 450 & 89.7 & -2.5 \\ -15.1 & 8.3 & -8.1 & -14.7 & 89.7 & 330 & 32.7 \\ -7.8 & 0.8 & 5.1 & -61.5 & -2.5 & 32.7 & 280 \end{bmatrix},$$  

where the above matrix representation of $H$ is with respect to the site basis $\{|m\rangle\}_{m=1}^{7}$, and the units of energy are cm$^{-1}$ (the typical units of choice in spectroscopy experiments). The diagonal terms in $H$ correspond to the site energies, and the off-diagonal terms correspond to intersite couplings. The order of magnitude of the energies in the above Hamiltonian is 100 cm$^{-1}$, implying that we should observe dynamics on the order of 300 femtoseconds (fs) (Fleming et al. experimentally observed behavior on this order in Ref. [13]).

Three Lindblad superoperators [45, 46] also contribute to the dynamics of the density operator in the nine-level model in Refs. [3, 4]. The general form of a Lindblad superoperator $\mathcal{L}(\rho)$ is

$$\mathcal{L}(\rho) \equiv \sum_{m} \zeta_{m} \left(2A_{m}^{\dagger}A_{m} - \{A_{m}^{\dagger}A_{m}, \rho\}\right),$$

where $\zeta_{m}$ is a rate and $A_{m}$ is a Lindblad operator [45, 46].

The first Lindblad superoperator $\mathcal{L}_{\text{diss}}$ in our model corresponds to the dissipative recombination of the exciton (loss of energy in the system):

$$\mathcal{L}_{\text{diss}}(\rho) \equiv \sum_{m=1}^{7} \Gamma_{m} \left(2|G\rangle \langle m| \rho |m\rangle \langle G| - \{|m\rangle \langle m|, \rho\}\right).$$  

An excitation at site $|m\rangle$ recombines with rate $\Gamma_{m}$, and $|G\rangle \langle m|$ is the Lindblad operator that effects this dissipation.

The next Lindblad superoperator $\mathcal{L}_{\text{sink}}(\rho)$ accounts for the trapping of the exciton in the reaction center:

$$\mathcal{L}_{\text{sink}}(\rho) \equiv \Gamma_{\text{sink}} \left(2|S\rangle \langle 3| \rho |3\rangle \langle S| - \{|3\rangle \langle 3|, \rho\}\right).$$  

The Lindblad superoperator $\mathcal{L}_{\text{sink}}$ includes the operator $|S\rangle \langle 3|$ because evidence suggests that site 3 in the FMO complex plays a crucial role in transferring the exciton to the reaction center [24], where it is later exploited for energy storage.

The final Lindblad superoperator $\mathcal{L}_{\text{deph}}$ accounts for the unavoidable dephasing interaction with the environ-
ment:
\[ L_{\text{deph}}(\rho) \equiv \sum_{m=1}^{7} \gamma_m (2|m\rangle \langle m| \rho |m\rangle \langle m| - |m\rangle \langle m| \rho), \]
where \( \gamma_m \) is the rate of dephasing at site \( m \). Discussion of this rough treatment of the decoherence appears in Refs. [13, 21, 47].

The following Lindblad quantum master equation governs the evolution of the density operator \( \rho \):
\[ \dot{\rho} = -i[H, \rho] + L_{\text{diss}}(\rho) + L_{\text{sink}}(\rho) + L_{\text{deph}}(\rho), \quad (10) \]
where we explicitly see the contribution of the Hamiltonian \( H \) and the noise superoperators (7-9) to the dynamics, and we implicitly set \( h = 1 \). Evolution according to the above Lindblad evolution equation is completely-positive and trace-preserving (CPTP) for any time \( t \), and we let \( N_{t, t_0}(\rho) \) denote the induced CPTP map corresponding to the evolution of the density operator \( \rho \) from an initial time \( t_0 \) to some later time \( t \).

IV. THE LEGGETT-GARG INEQUALITY AND THE FMO COMPLEX

In the forthcoming subsections, we consider the application of the Leggett-Garg inequality to the FMO complex. We first discuss several observables that one might measure in a Leggett-Garg protocol. We then obtain analytical results when the dynamics are purely coherent. These analytical results allow us to determine the time intervals between measurements in a Leggett-Garg protocol that lead to the stongest violation of the inequality. We finally use these time intervals in a numerical simulation of the FMO dynamics that includes the effects of noise. The result is that several observables exhibit a strong violation of the inequality for temperatures below room temperature, and the violation persists in some cases up to temperature.

A. Observable for the Leggett-Garg Inequality in the FMO Complex

Recall that the Leggett-Garg quantity in (11) involves any three dichotomic observables \( Q(t_1), Q(t_2), \) and \( Q(t_3) \) measured at respective times \( t_1, t_2, \) and \( t_3 \).

We have freedom in choosing both the observables that we measure and the times at which we measure them. Perhaps the simplest dichotomic observable that we can construct corresponds to the question [41]:

"Is the system in state \( |\psi\rangle \) or not?"

The two-element set of measurement operators for this question are as follows: \( \{|\psi\rangle \langle \psi|, I - |\psi\rangle \langle \psi|\} \). We assign the value \(+1\) if the system is in the state \( |\psi\rangle \) and the value \(-1\) otherwise. Let \( Q(|\psi\rangle) \) denote the resulting observable where
\[ Q(|\psi\rangle) \equiv |\psi\rangle \langle \psi| - (I - |\psi\rangle \langle \psi|) = 2|\psi\rangle \langle \psi| - I. \quad (11) \]

We might build a dichotomic observable from states in the exciton basis. The exciton basis is the energy eigenbasis \( \{|\phi_m\rangle\}_{m=1}^7 \) of the Hamiltonian \( H \) in (6), where
\[ \forall m \quad H|\phi_m\rangle = E_m|\phi_m\rangle. \]

Then the dichotomic observable constructed from an energy eigenstate is \( Q(|\phi_m\rangle) \). Note that observables of this form commute with the Hamiltonian \( H \) in (6).

Another possibility is to build the dichotomic observable from the site basis. This type of observable asks the question, "Is the excitation at site \( m \) or not?" where \( m \in \{G, 1, \ldots, 7, S\} \). The dichotomic observable constructed from a site state is the site observable \( Q(m) \). Observables of this form do not commute with the Hamiltonian \( H \) in (6).

B. Analytical Results for Coherent Dynamics

Let us first suppose that evolution of the FMO complex is coherent and does not include the noisy Lindblad evolution terms in (7-9). This assumption is unrealistic, but it gives a starting point for understanding the Leggett-Garg inequality and the FMO complex before proceeding with the full-blown evolution in (10).

The general form of the two-time correlation functions appearing in the Leggett-Garg quantity \( K \) in (1) are as follows for a coherent evolution:
\[ C_{1,2} = \frac{1}{2} \text{Tr} \left[ Q(t_2) e^{-iH(t_2-t_1)} \{ Q(t_1), \rho_{t_1} \} e^{iH(t_2-t_1)} \right], \]
\[ C_{2,3} = \frac{1}{2} \text{Tr} \left[ Q(t_3) e^{-iH(t_3-t_2)} \{ Q(t_2), \rho_{t_2} \} e^{iH(t_3-t_2)} \right], \]
\[ C_{1,3} = \frac{1}{2} \text{Tr} \left[ Q(t_3) e^{-iH(t_3-t_1)} \{ Q(t_1), \rho_{t_1} \} e^{iH(t_3-t_1)} \right], \]
where \( H \) is the Hamiltonian in (6), \( \rho_{t_1} \) is the initial density operator of the FMO complex, \( \rho_{t_2} \equiv e^{-iH(t_2-t_1)} \rho_{t_1} e^{iH(t_2-t_1)} \), and \( \{ \cdot, \cdot \} \) is the anticommutator. As indicated in Section II, the correlator \( C_{1,3} \) characterizes an experiment in which measurements occur at times \( t_1 \) and \( t_3 \) but no measurement occurs at time \( t_2 \).

Suppose first that we prepare the FMO complex in some state \( |\psi\rangle \) and take the Leggett-Garg observable to be \( Q(|\psi\rangle) \) as in (11). Thus, this measurement is a "survival probability" measurement [41, 48, 49]. Suppose further that we measure \( Q(|\psi\rangle) \) at uniform time intervals \( \Delta t \). A straightforward calculation [48, 49] shows that the Leggett-Garg quantity in (3) is equal to
\[ 4 \left| \langle \psi| \psi_{2\Delta t} \rangle \right|^2 - 4 \text{Re} \left( \langle \psi| \psi_{\Delta t} \rangle \langle \psi_{\Delta t}| \psi \rangle \right), \quad (12) \]
where \( \psi_{\Delta t} \equiv e^{-iH\Delta t} |\psi\rangle \). Recall that a violation of the Leggett-Garg inequality occurs when the above quantity drops below zero.
FIG. 1: (Color online) The Leggett-Garg quantity as a function of the uniform time interval $\Delta t$ for all seven sites in the FMO complex when evolution is coherent and the initial state is the classical mixture $\rho_{1,6}$. The units of $\Delta t$ are picoseconds. A dotted line divides each plot into two regions. Points above a dotted line are in a “no violation” region, while points below are in a “violation” region. The convention is the same in Figures 2, 3, and 4. To show overall behavior, the $\Delta t$ axis has a coarse scale up to five picoseconds (ps). However, an experimental test would require control of $\Delta t$ to hundreds of femtoseconds.

TABLE I: The first column lists the initial state of the FMO complex. The second column lists the site that we measure in a Leggett-Garg protocol. The third column gives the analytical form of the corresponding Leggett-Garg quantity as a function of the uniform time interval $\Delta t$ when dynamics are purely coherent. We use these formulas to compute the results of Figure 1 and Table II.

If the state $|\psi\rangle$ is an eigenstate $|\phi_m\rangle$ in the exciton basis we should not expect to violate the Leggett-Garg inequality because the observable $Q_{|\phi_m\rangle}$ commutes with the Hamiltonian. We can confirm this intuition by plugging the eigenstate $|\phi_m\rangle$ into (12). Doing so gives a value of zero for (12), thereby saturating the Leggett-Garg inequality, but yielding no violation.

Thus, we set the Leggett-Garg observable to a site observable $Q_{|m\rangle}$ where $m \in \{1, \ldots, 7\}$. Sites 1 and 6 are the chromophores that are closest to the chlorosome antenna and are thus most likely to be the initial state of the FMO complex (13). The initial state $\rho_{1,6}$ of the FMO complex can be a pure state $|1\rangle \langle 1|$ or $|6\rangle \langle 6|$ or a uniform classical mixture of sites $|1\rangle$ and $|6\rangle$:

$$\pi_{1,6} \equiv \frac{1}{2} \left( |1\rangle \langle 1| + |6\rangle \langle 6| \right).$$

One might also consider setting the initial state to the
Table II: The first column lists the initial state of the FMO complex. The second column lists the site observable that the Leggett-Garg protocol measures. The third column lists the strongest violations for each site observable, and the fourth column gives the corresponding time interval $\Delta t$ that leads to this violation. (For comparison, the strongest possible violation of the inequality is $-0.5$.) We obtained these values assuming that evolution is coherent (though, we examined times up to $5 \text{ ps}$ only). The last row in the table indicates that we do not obtain a violation for any site observable when the initial state is the maximally mixed state.

$\pi \equiv \frac{1}{7} \left( |1\rangle \langle 1| + \cdots + |7\rangle \langle 7| \right)$.

Table II lists exact expressions for the Leggett-Garg quantity in (13) for these different cases.

Figure 1 plots the Leggett-Garg quantity for each site observable as a function of the uniform time interval $\Delta t$, when the initial state is $\pi_{1,6}$. The result is that each of the seven site measurements gives a violation of the Leggett-Garg inequality for some intervals $\Delta t$ when the dynamics are purely coherent. These results may not be particularly surprising given that the system is quantum, the measurements are sharp, and the dynamics are purely coherent.

Table III lists the time intervals that lead to the strongest violation for $\Delta t \in [0, 5] \text{ ps}$. We only consider times up to five picoseconds (ps) because it is likely that the exciton will trap by this time for the case of incoherent dynamics in the next section. Table III also lists the time intervals that lead to the strongest violation when the initial state is $|1\rangle \langle 1|$, $|6\rangle \langle 6|$, or $\pi$. We now use these time intervals for the more realistic case, where the excitation in the FMO complex experiences the noisy contributions in (19) from dissipation and dephasing.

C. Numerical Results for Incoherent Dynamics

The Lindblad evolution in (10) is a more realistic model for evolution of the excitation in the FMO complex. It incorporates the effects of excitonic recombination, trapping to the reaction center, and environmental dephasing noise, albeit in a Markovian context. The two-time correlation functions appearing in the Leggett-Garg quantity $K$ in (10) must now be evaluated using the following more general forms:

$$C_{1,2} = \frac{1}{2} \text{Tr} \left[ (Q \circ_{t_2} N_{t_2,t_1} \{ (Q \circ_{t_1} \rho) \} \right],$$

$$C_{2,3} = \frac{1}{2} \text{Tr} \left[ (Q \circ_{t_3} N_{t_3,t_2} \{ (Q \circ_{t_2} \rho) \} \right],$$

$$C_{1,3} = \frac{1}{2} \text{Tr} \left[ (Q \circ_{t_3} N_{t_3,t_1} \{ (Q \circ_{t_1} \rho) \} \right],$$

where $\mathcal{N}$ is the superoperator that propagates the density operator forward in time according to the evolution in (10).

In order to perform a numerical simulation for the incoherent dynamics (10), we need to fix the trapping rate $\Gamma_{\text{sink}}$, the recombination rates $\Gamma_{m}$, and the dephasing rates $\gamma_{m}$. We take these rates from Refs. [5, 6]. Unless otherwise stated, the trapping rate $\Gamma_{\text{sink}} = 62.8/1.88 \text{ cm}^{-1}$, corresponding to about $2\pi \cdot c \cdot \Gamma_{\text{sink}} \approx 5 \times 10^{-4} \text{ ps}^{-1}$. The recombination rates $\Gamma_{m}$ are uniform for all sites in the FMO complex so that $\Gamma_{m} = \Gamma_{\text{recomb}} = 1/ (2 \cdot 188) \text{ cm}^{-1}$, corresponding to about $2\pi \cdot c \cdot \Gamma_{\text{recomb}} \approx 5 \times 10^{-4} \text{ ps}^{-1}$. We assume that the dephasing rate is uniform so that $\gamma_{m} = \gamma$ for all sites $m$.

As in the previous subsection, we choose the Leggett-Garg observable to be a site observable $Q_{m}$ where $m \in \{1, \ldots, 7\}$. The initial state $\rho_{1}$ can either be the pure state $|1\rangle \langle 1|$, $|6\rangle \langle 6|$, or a uniform classical mixture of sites $\{1\}$ and $\{6\}$ as in (13), for the same reasons mentioned in the previous subsection (we do not consider the maximally mixed state because there is no phenomenological evidence for this case, and furthermore, it does not give a violation even in the coherent case). The time interval $\Delta t$ between measurements of the Leggett-Garg observable is taken from Table III. Figures 2 and 3 display the Leggett-Garg quantity as a function of the dephasing parameter $\gamma$ for each site observable $Q_{m}$, where $m \in \{1, \ldots, 7\}$.

The figures demonstrate that several site observables exhibit a violation even as $\gamma$ increases. The temperature analysis of the environment in Ref. [15] indicates that a
dephasing rate of 2.1 ps$^{-1}$ corresponds to a temperature of around 77°C and a dephasing rate of 9.1 ps$^{-1}$ corresponds to a temperature of 298°C (room temperature). Under the assumption that this is approximately correct, Figures 2, 3 and 4 predict a violation at both temperatures. However, it might be difficult for an experimentalist to observe these violations at room temperature given that they are weak.

We have verified the robustness of these predictions against variations in the dynamical parameters in Ref. \[24\]. Ref. \[24\] mentions that the site energies of their calculated Hamiltonian are accurate within ±2 cm$^{-1}$. We therefore conducted several simulations that added independent, zero-mean Gaussian noise with variance 2 to each entry in the Hamiltonian matrix in \[10\] to determine if the violations would still hold under this slight perturbation. The result is that all room temperature violations in Figures 2, 3 and 4 still hold, and in fact, the values of the Leggett-Garg quantities are the same up to the fourth decimal place. The trapping rates in the literature vary substantially, including 0.25 ps$^{-1}$ \[24\], 1 ps$^{-1}$ \[12\], or 4 ps$^{-1}$ \[16\], so we have checked our results for all of these choices. The plots for all these cases are similar.
to Figures 2, 3, and 4 and have approximately the same values for violations at room temperature. This finding is reasonable given that most of our measurement times are less than the average trapping times corresponding to these other trapping rates.

Our numerical simulations demonstrate that several choices of measurements lead to a violation of the Leggett-Garg inequality even when noise processes act on an excitation in the FMO complex. Experimental confirmation could irrevocably exclude a class of macrorealistic theories from describing the dynamics of the excitation.

V. CONCLUSIONS

We have framed tests that could be used to experimentally exclude a class of macrorealistic theories, including a classical incoherent hopping model, from describing the room-temperature dynamical behavior of an excitation in the FMO complex. To do so, we have introduced several examples of observables that one might apply in a test of macrorealism, and our numerical simulations predict that these observables lead to a violation of the Leggett-Garg inequality.

We discuss several ideas for furthering this research. The Leggett-Garg measurements that we have considered here are projective measurements. In practice, an experimentalist is unlikely to realize such an idealized measurement. An experimentalist is more likely able only to effect a “noisy” or “fuzzy” measurement of the sites in the FMO complex. Along these lines, Kofler et al. have shown that “fuzzy” measurements may lead to our observation of a classical world even in the presence of quantum dynamics [48, 49]. Future work should formulate Leggett-Garg inequalities involving quantities that are conveniently accessible to FMO experimentalists (measurements in the site basis are currently infeasible [50]) and should consider the limits of experimental measurement capabilities. Furthermore, future work should consider more realistic models of noise in the FMO complex, potentially including correlated noise [22, 51] and non-Markovian effects [26].

One might consider an application of Bell’s inequality to study the ability of the FMO complex to preserve entanglement.

We have applied the Leggett-Garg inequality to the FMO complex, and it would be valuable to apply the Leggett-Garg test to the dynamics of magnetoreception in the avian compass [6, 8, 9, 10]. It would also be interesting to explore the Leggett-Garg inequality in artificial quantum networks with particular noisy interactions. A study of this sort might lead to an increased understanding of the dividing line between macrorealism and nonclassicality in more complicated systems. One might be able to apply the ideas in Refs. 2, 3, 4, 48, 49 here.

Acknowledgments

The authors thank Andrew Cross, Alan Aspuru-Guzik, Kevin Obenland, Patrick Rebentrost, and Leslie Vogt for useful discussions and thank Science Applications International Corporation for supporting this scientific research. MMW is especially grateful to Alan Aspuru-Guzik and Patrick Rebentrost for their warm hospitality during his visit to Harvard and Leslie Vogt for her suggestion to consider Leggett-Garg measurement time intervals within the average trapping time of an exciton.
