(Dated: September 12, 2018)

I show how applying a symplectic Gram-Schmidt orthogonalization to the normalizer of a quantum code gives a different way of determining the code’s logical operators. This approach may be more natural in the setting where we produce a quantum code from classical codes because the generator matrices of the classical codes form the normalizer of the resulting quantum code. This technique is particularly useful in determining the logical operators of an entanglement-assisted code produced from two classical binary codes or from one classical quaternary code. Finally, this approach gives additional formulas for computing the amount of entanglement that an entanglement-assisted code requires.

Keywords: logical operators, symplectic Gram-Schmidt orthogonalization, entanglement-assisted quantum error-correcting codes

I. INTRODUCTION

The logical operators of a quantum code are important for fault-tolerant quantum computation [1] and in the simulation of the performance of stabilizer quantum error-correcting codes [2]. The typical method for determining the logical operators of a quantum code is to employ Gottesman’s algorithm [3]. This algorithm brings the stabilizer of a quantum code into a standard form and extracts the logical operators from this standard form.

In this paper, I provide another technique for determining the logical operators of a quantum code. This technique begins with the "normalizer" of the code and is perhaps more natural in the setting where we produce a CSS quantum code from two classical additive binary codes [4, 5] or where we produce a CRSS quantum code from one classical additive code over GF(4) [6]. In both of these cases, we possess the full normalizer of the resulting quantum code because the generator matrices of the classical codes form its normalizer. Additionally, I show that this technique is useful in determining the logical operators of an entanglement-assisted code [7, 8], a type of quantum code to which Gottesman’s algorithm does not apply. The technique is again natural in the setting where we import classical codes because the generator matrices form the full normalizer of the resulting quantum code. This technique also gives another way of computing the amount of entanglement that a given entanglement-assisted code requires. The computation of the formulas in this paper may be more efficient than those in Ref. [9] and the efficiency depends on the parameters of a given code. The technique for computing the logical operators and the entanglement formulas in this paper should be a useful addition to the quantum code designer’s toolbox.

II. REVIEW OF THE SYMPLECTIC GRAM-SCHMIDT ORTHOGONALIZATION PROCEDURE

I first review the symplectic Gram-Schmidt orthogonalization procedure (SGSOP) before proceeding to the main development of this paper. The SGSOP is equivalent to finding a standard symplectic basis for a set of vectors [10]. It has made appearances in the quantum information literature in entanglement-assisted quantum coding [11, 12], in finding an entanglement measure for a stabilizer state [11], in the simulation of measurement outcomes of stabilizer codes [12], and in the decomposition of subsystem codes [13].

We begin with a set of $m$ Pauli generators $g_1, \ldots , g_m$ that do not necessarily form a commuting set. Consider generator $g_1$. There are two possible cases for this generator:

1. Generator $g_1$ commutes with all other generators $g_2, \ldots , g_m$. Set it aside in a “set of processed generators”, relabel generators $g_2, \ldots , g_m$ as respective generators $g_1, \ldots , g_{m-1}$ and repeat the SGSOP on these remaining generators.

2. Generator $g_1$ anticommutes with some other generator $g_j$ where $2 \leq j \leq m$. Relabel $g_j$ as $g_2$ and vice versa. Modify the other generators as follows:

$$\forall i \in \{3, \ldots , m\} \quad g_i = g_1 \cdot g_{(g_1,g_2)} \cdot g_{(g_1,g_j)}$$

where the function $f$ is equal to zero if its two arguments commute and is equal to one if its two arguments anticommute. (Note that we are not
concerned with the overall phases of any of the generators in this paper.) The new generators \( g_3, \ldots, g_m \) then commute with \( g_1 \) and \( g_2 \). Place \( g_1 \) and \( g_2 \) into the “set of processed generators,” relabel generators \( g_1, \ldots, g_m \) as respective generators \( g_1, \ldots, g_{m-2} \), and repeat the SGSOP on these remaining generators.

The result of the SGSOP is to produce a set of \( m \) processed generators where \( 2c \) of them form anticommuting pairs (each pair commuting with the generators in the other pairs) and \( l \) of them commute with themselves and the \( c \) pairs of generators. It is a reversible algorithm, meaning that we can recover the original set of generators by performing all of the steps in reverse, and its complexity is \( O\left(\sum_{i=1}^{n} j^{2} + \sum_{i=1}^{n} j^{2} \cdot m^{2}\right) \). This complexity is the same as the complexity of Gottesman’s algorithm for bringing the generating set of \( \mathbb{Z}_{2} \) into the “set of processed generators,” relabel generators in this paper.) The new generators \( g_3 \) and \( g_4 \) commute with \( g_1 \) and \( g_2 \). Place \( g_1 \) and \( g_2 \) into the “set of processed generators,” relabel generators \( g_1, \ldots, g_m \) as respective generators \( g_1, \ldots, g_{m-2} \), and repeat the SGSOP on these remaining generators.

The idea of the proof is that the application of the SGSOP to the normalizer matrix \( N \) transforms the matrix \( \Omega_N \) to the following standard form:

\[
\bigoplus_{i=1}^{k} J_{n-k} \bigoplus_{j=1}^{k} [0],
\]

where the small and large \( \oplus \) correspond to the direct sum operation, \( J \) is the matrix

\[
J = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix},
\]

and \( [0] \) is the one-element zero matrix. Each matrix \( J \) in the direct sum corresponds to a symplectic pair and has rank two. Each symplectic pair corresponds to exactly one logical operator in the code. Each matrix \( [0] \) has rank zero and corresponds to an ancilla qubit. See Ref. [8] for more details.

III. GENERAL STABILIZER CODES

We now consider applying the SGSOP to the normalizer \( N(S) \) of a stabilizer code \( S \) with stabilizer \( S \). The result is that the SGSOP gives a different way for determining the logical operators of a given stabilizer code.

Suppose that we have a set \( \langle S \rangle \) of \( n \) Pauli generators where each Pauli generator in \( \langle S \rangle \) is an \( n \)-fold tensor product of Pauli matrices. Suppose furthermore that \( \langle S \rangle \) generates an abelian group. Suppose we also have a generating set \( \langle N(S) \rangle \) of \( p \) elements where \( p > n - k \) and \( \langle N(S) \rangle \) generates the normalizer \( N(S) \) of the stabilizer \( S \). The relation \( S \subseteq N(S) \) holds for this case because the set of generators in \( \langle S \rangle \) generates an abelian group.

We can perform the SGSOP on the generating set \( \langle N(S) \rangle \). The SGSOP divides \( \langle N(S) \rangle \) into two different sets: the logical generating set \( \langle S_L \rangle \) and the stabilizer generating set \( \langle S \rangle \). We can write the latter generating set as \( \langle S \rangle \) because it generates the same group that the generating set from the previous paragraph generates. The logical generating set \( \langle S_L \rangle \) consists of \( k \) anticommuting pairs of generators that correspond to the logical operators for the stabilizer code \( S \). The size of the generating set \( \langle N(S) \rangle \) is then \( p = n - k + 2k = n + k \).

We can also think about the code in terms of binary vectors that represent it \( [3, 14] \). Suppose we have the normalizer matrix:

\[
N \equiv \begin{bmatrix} N_Z & N_X \end{bmatrix},
\]

where \( N \) is the binary representation of the generators in \( \langle N(S) \rangle \). We can consider the “symplectic product matrix” \( \Omega_N \) where

\[
\Omega_N \equiv N_Z N_X^T + N_X N_Z^T,
\]

and addition is binary. It is then straightforward to show by the method of proof of Theorem 1 in Ref. \( [8] \) that

\[
\frac{1}{2} \text{rank}(\Omega_N) = k.
\]

The typical method for constructing a CSS quantum code is to build the following stabilizer matrix:

\[
\begin{bmatrix} H_1 & 0 \\ 0 & H_2 \end{bmatrix}
\]

The code forms a valid stabilizer matrix because \( H_1 H_2^T = 0 \) (this condition corresponds to the requirement for a stabilizer code to consist of a commuting set of generators).

The number of generators in the CSS quantum code is equal to \( 2n - k_1 - k_2 \), and it therefore has \( n - (2n - k_1 - k_2) = k_1 + k_2 - n \) logical qubits with \( 2(k_1 + k_2 - n) \) logical operators. The size of the normalizer is thus \( (2n - k_1 - k_2) + 2(k_1 + k_2 - n) = k_1 + k_2 \).

There is another way to build the code by exploiting the generator matrices \( G_1 \) and \( G_2 \). The below matrix is the normalizer matrix of the code:

\[
\begin{bmatrix} 0 & G_1 \\ G_2 & 0 \end{bmatrix}.
\]
The conditions $H_1 G_1^T = 0$ and $H_2 G_2^T = 0$ guarantee that the above matrix is a valid normalizer matrix. It represents the full normalizer for the code because the rows are linearly independent and the number of generators in the normalizer is $k_1 + k_2$.

Suppose that we run the SGSOP on the rows of the normalizer matrix in (3). The procedure then produces $k_1 + k_2 - n$ anticommuting pairs and $n - k_1 + n - k_2$ commuting generators. The $k_1 + k_2 - n$ anticommuting pairs correspond to $2(k_1 + k_2 - n)$ logical operators for the code, and the $n - k_1 + n - k_2$ commuting generators correspond to the stabilizer generators of the code. This technique for obtaining the logical operators and the stabilizer generators in the case of a CSS code is perhaps more natural than applying Gottesman’s method in Ref. [8] because we already know the matrices $G_1$ and $G_2$ when importing classical codes.

By the same method of proof as Corollary 1 in Ref. [9], the following formula also holds for any CSS code

$$\text{rank}(G_1 G_2^T) = k_1 + k_2 - n,$$

because this quantity captures the amount of anticommutativity in the generators in (3).

**B. CRSS Quantum Codes**

A CRSS quantum code is one that we create by importing a classical additive code over GF(4) [6]. Suppose a GF(4) code has parity check matrix $H$ and generator matrix $G$ where $HG^T = 0$. Additionally, suppose that the code is dual under the trace product over GF(4), i.e., the following condition holds:

$$\text{tr}\left\{H H^\dagger\right\} = 0,$$

where the dagger symbol $\dagger$ is the conjugate transpose of matrices over GF(4) and the null matrix on the right has dimension $(n - k) \times (n - k)$. Note that the above trace operation is different from the standard matrix trace, but is rather an elementwise computation of the trace product over GF(4) [6].

We can then create a quantum check matrix:

$$\gamma \left( \begin{bmatrix} \omega H \\ \overline{\omega} H \end{bmatrix} \right),$$

where $\gamma$ is the isomorphism that takes an $n$-dimensional vector over GF(4) to a $n$-fold tensor product of Pauli operators [8].

It is straightforward to determine the normalizer of such a code because we can construct it from the generator matrix $G$:

$$\begin{bmatrix} \omega G^* \\ \overline{\omega} G^* \end{bmatrix}.$$  

The above matrix is a valid normalizer for the resulting quantum code because

$$\text{tr}\left\{\omega H \begin{bmatrix} \omega G^* \\ \overline{\omega} G^* \end{bmatrix}^\dagger\right\} = \text{tr}\left\{\omega H \begin{bmatrix} \omega G^T & \omega G^T \end{bmatrix}\right\} = \text{tr}\left\{\begin{bmatrix} H G^T & \overline{\omega} H G^T \end{bmatrix}\right\} = \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix},$$

where the first equality is by definition of the conjugate transpose, the second equality holds because $\omega \overline{\omega} = 1$, $\omega = \overline{\omega} = \omega$ for elements of GF(4). The last equality follows from the condition $HG^T = 0$.

We then can perform the SGSOP on the above normalizer matrix in (6). The result of the algorithm is to produce $2(2k - n)$ anticommuting pairs and $2(n - k)$ generators that commute with themselves and the pairs. This method again determines the logical operators for the imported code and may be a more natural alternative to Gottesman’s method because we already know the matrix $G$ that determines the normalizer for the resulting CRSS quantum code.

By the same method of proof as Corollary 2 in Ref. [9], the following formula holds for a trace-orthogonal code imported from GF(4):

$$\text{rank}(GG^T) = 2k - n.$$  

**IV. ENTANGLEMENT-ASSISTED QUANTUM CODES**

We can extend this procedure to an entanglement-assisted code as well. This alternative procedure for determining the logical operators is useful here because Gottesman’s method does not apply to a nonabelian group of Pauli generators.

Suppose that we have a set $\langle S \rangle$ of $m$ Pauli generators that represents a generating set of operators with desirable error-correcting properties. The generating set $\langle S \rangle$ does not necessarily generate an abelian group. Suppose we also have a generating set $\langle N(S) \rangle$ of $p$ elements. This generating set $\langle N(S) \rangle$ generates the normalizer $N(S)$ of the stabilizer $S$. In general, the relation $S \subseteq N(S)$ does not necessarily hold for this case because the set of generators in $\langle S \rangle$ is not an abelian group.

We can perform the SGSOP on the generators in $\langle S \rangle$. This procedure divides $\langle S \rangle$ into two sets of generators: the entanglement generator set $\langle S_E \rangle$ and the isotropic generator set $\langle S_I \rangle$. The set $\langle S_E \rangle$ contains anticommuting pairs of generators (where generators different pairs commute), and the set $\langle S_I \rangle$ contains a commuting set of generators that furthermore commute with the generators in $\langle S_E \rangle$. The size of the generating set $\langle S_E \rangle$ is $2c$, and the size of the set $\langle S_I \rangle$ is $i$ so that $m = i + 2c$.

We can also perform the SGSOP on the generating set $\langle N(S) \rangle$. The SGSOP divides this generating set into
two sets: the logical generating set \( (S_L) \) and the isotropic generating set \((S_I)\). We can write this isotropic generating set as \((S_I)\) because it generates the same group as the group generated by the isotropic generating set from the previous paragraph. The size of the generating set \( \langle N (S) \rangle \) is then \( p = i + 2l \). The generators in the logical generating set \((S_L)\) are the logical operators for the code.

We can again consider this procedure in the binary vector representation. Suppose the following matrix specifies the normalizer matrix:

\[
N \equiv \begin{bmatrix} N_Z & N_X \end{bmatrix}.
\]

Consider the matrix \( \Omega_N \) where

\[
\Omega_N \equiv N_Z N_X^T + N_X N_Z^T,
\]

and addition is binary. By the same method of proof as Theorem 1 in Ref. \[9\], we can show that

\[
\frac{1}{2} \text{rank}(\Omega_N) = l.
\]

### A. CSS Entanglement-Assisted Codes

We now consider extending the development in Section IV to the formulation of a CSS entanglement-assisted code \[2\, 8\]. This extension gives a useful way for determining the logical operators of a CSS entanglement-assisted quantum code. Additionally, we determine a formula, different from that in Corollary 1 of Ref. \[9\], for computing the amount of entanglement that a given CSS entanglement-assisted quantum code requires.

Consider two arbitrary additive binary codes \( C_1 \) and \( C_2 \) with respective parity check matrices \( H_1 \) and \( H_2 \) and respective generator matrices \( G_1 \) and \( G_2 \). We can form a quantum check matrix as follows:

\[
\begin{bmatrix} H_1 & 0 \\ 0 & H_2 \end{bmatrix}.
\]

The above matrix is not a valid stabilizer matrix, but we can run the SGSOP on it to determine how to add entanglement in order to make this code a valid stabilizer code. After adding ebits to the code, it then becomes an entanglement-assisted stabilizer code. A CSS entanglement-assisted code constructed in this way has \( 2n - k_1 - k_2 \) generators \( (2c \) of which form anticommuting pairs and \( 2n - k_1 - k_2 - 2c \) form the isotropic generating set), \( k_1 + k_2 - n + c \) logical qubits, and consumes \( c \) ebits \[7\].

The normalizer of the generators in \[8\] is again

\[
\begin{bmatrix} 0 & G_1 \\ G_2 & 0 \end{bmatrix},
\]

and represents the full normalizer of the generators in \[8\] because the number of generators is \( k_1 + k_2 \) and the rows are linearly independent. This time, when we run the algorithm, we get \( 2(k_1 + k_2 - n + c) \) anticommuting pairs and \( n - k_1 + n - k_2 - 2c \) commuting generators. The commuting generators form the basis for the isotropic generating set of the code and the anticommuting generators correspond to the logical operators of the code.

By the method of proof of Corollary 1 in Ref. \[6\], we can show that the following relation holds:

\[
\text{rank}(G_1 G_1^T) = k_1 + k_2 - n + c.
\]

This formula gives us another way to determine the amount of ebits that a given entanglement-assisted code requires because the parameters \( n, k_1, \) and \( k_2 \) are known parameters.

The complexity of the computation in \[9\] is \( O(k_1k_2n) \). A similar formula from Ref. \[9\] computes the amount of entanglement that the code requires:

\[
\text{rank}(H_1 H_2^T) = c.
\]

The complexity of the above formula is \( O((n-k_1)(n-k_2)n) \). Thus, the formula in \[9\] may provide a speedup for low-rate codes. It is up to the quantum code designer to decide which formula to use depending on the parameters of the code.

### B. CRSS Entanglement-Assisted Codes

The method for constructing a CRSS entanglement-assisted code is again to import an additive classical code over \( \text{GF}(4) \). Suppose the imported code has parity check matrix \( H \) and generator matrix \( G \) so that \( HG^T = 0 \). The imported code does not have to be orthogonal with respect to the trace product. We then create a quantum check matrix:

\[
\gamma\begin{bmatrix} \omega H \\ \bar{\omega} H \end{bmatrix},
\]

where \( \gamma \) is the same isomorphism as in \[5\].

The normalizer of the code is again the same as in \[8\].

The normalize matrix is

\[
\gamma\begin{bmatrix} \omega G^* \\ \bar{\omega} G^* \end{bmatrix},
\]

and it is a valid normalizer for the same reasons as in \[8\].

Performing the symplectic Gram-Schmidt orthogonalization procedure on the normalizer matrix, we then get \( 2(2k - n + c) \) anticommuting pairs and \( 2(n - k - c) \) commuting generators. This method again determines the logical operators for the imported code.

By the same method of proof as Corollary 2 in Ref. \[6\], we can show that the following formula holds:

\[
\text{rank}(GG^T) = 2k - n + c.
\]

The formula gives another way for determining the amount of entanglement that an entanglement-assisted
quantum code requires because the parameters $k$ and $n$ are known parameters.

The complexity of the computation of rank$(GG^†)$ is $O(k^2n)$. A similar formula from Ref. [1] computes the amount of entanglement that the codes requires:

$$\text{rank}(HH^†) = c.$$ 

The complexity of the above formula is $O((n − k)^2 n)$. Thus, the formula in [10] may again provide a speedup for low-rate codes.

V. CONCLUSION

I have shown how the normalizer of a quantum code, whether stabilizer or entanglement-assisted, gives a useful way for determining its logical operators. It is natural to assume full knowledge of the normalizer in the case where we import classical codes to produce quantum codes. Additionally, this development gives formulas for computing the amount of entanglement that an entanglement-assisted code requires, and these formulas are an alternative to those given in Ref. [9]. It is straightforward to extend these methods and formulas to qudit codes and continuous-variable codes, by glancing at the results in Ref. [9].

Future work includes determining how to apply these findings in the setting of quantum convolutional codes [12, 16] and entanglement-assisted quantum convolutional codes [17]. Todd Brun and I have made attempts at this problem by devising the algorithm in Section IV-D of Ref. [18] for the CSS case and the expansion technique and polynomial symplectic Gram-Schmidt algorithm in respective Sections IV and V of Ref. [19] for the CRSS case. It is more complicated in the convolutional setting because we would like to maintain the periodic structure of the quantum convolutional code while still maintaining the standard symplectic relations. An algorithm that achieves both tasks would be a boon to the theory of quantum convolutional coding.
